The plates, having been carefully cleaned in the ordinary manner, and treated with talc, may be edged with a solution of rubber in benzole. (In our experiments this precaution did not appear indispensable). They are then covered with the liquid emulsion, the operator manipulating with rather more care than in working with wet collodion, and the films set to dry. Our experiments prove that these plates may be employed wet; their rapidity is then much greater than when dry. The time they will keep has not yet been determined. The film should be opaline and slightly brilliant. Matt and porcelain films rarely give good results.

The time of exposure appears diminished by two-thirds when these plates are compared with ordinary dry plates, such, for instance, as tannin or albumen (Taupenot) films. It is about double that required by a good collodion worked wet. The prints are remarkable for the delicacy and details of their half-tones.

The development is undertaken by the aid of the following solutions:—

- | | | | |
|-------------------------|-----|-----|------------------|
| 1.—Carbonate of ammonia | ... | ... | 20 grammes |
| Bromide of potassium | ... | ... | 0.40 " |
| Water | ... | ... | 1000 cub. cents. |

The carbonate of ammonia which is dissolved should be in a state of sesqui-carbonate—that is to say, in hard and transparent pieces—and should not have passed into the condition of bicarbonate, when it becomes opaque and friable. In this condition it develops only with great difficulty.

- | | | | |
|--------------------|-----|-----|-----------------|
| 2.—Pyrogallie acid | ... | ... | 10 grammes |
| Alcohol | ... | ... | 100 cub. cents. |

The development is commenced by covering the sensitive surface with a film of alcohol, which is poured back into a vessel, and may be employed afterwards for other plates. In this way the cinchonine or quinine is dissolved, and the pores of the collodion film are opened. The surface is rinsed with alcohol carefully until water will run uniformly over the surface. The plate is then put into a bath, and covers red with a mixture, made at the time, of one hundred parts of the ammoniacal solution, and two or three parts of the pyrogallie solution. Under the influence of this mixture the image rapidly appears, and will not fog if the manipulation is well carried out. As soon as all the details have come out, the intensifying mixture is at once added:—

- | | | |
|--------------------------|-----|--------------------|
| 1.—Distilled water | ... | 100 cub. cents. |
| Bromide of potassium | ... | 1 gramme |
| 2.—Bicarbonate of potash | ... | Saturated solution |
| 3.—Distilled water | ... | 75 cub. cents. |
| Alcohol | ... | 25 " " |
| Glucose | ... | 10 grammes. |

The mixture is made by taking equal proportions of the three solutions, about five cubic centimetres of each being required for one hundred cubic centimetres of alkaline developer. The bromide of potassium protects the negative from fog, and must be carefully handled. The glucose adds to the intensity of the image, and may be added in larger quantity, according to necessity.

The image acquires its proper intensity in a few seconds, and it must be borne in mind that the cliché gains in vigour on drying, after it has been fixed. The development must not be pushed too far, therefore. The cliché, as finished, is fixed with hyposulphite of soda, which is done

a very little while, and finally washed and dried. If necessary, it may easily be detached from the glass by means of gelatine.

Such are the formulae and manipulations employed by M. Chardon. The experiments made by us (the reporting committee), under the conditions prescribed by M. Chardon, have given the most conclusive results. Consequently, M. Chardon has complied with the conditions of the competition in making public his whole method of operating.

After conducting several experiments with a view to testing the process, the committee have unanimously come to the conclusion that M. Chardon is entitled to the prize, and recommend, therefore, its award to that gentleman.

SCIENCE AND WAR.

MR. BADEN PRITCHARD, writing in a recent number of *Nature*, calls attention to the part science, and especially the camera, has played in war. He says:—

"Recent wars have had particular interest for the man of science. Starting from the close of the Crimean war, the first in which the electric telegraph was employed, we find ample examples of the assistance furnished to the soldier by scientific research. One instance taken from the war of 1858 is especially interesting. The Austrians held Venice at the time, it may be remembered, and to protect the harbour torpedoes were laid down. The torpedoes were fired by electricity, and contained gun-cotton, this being the first instance on record of the employment of electric torpedoes and of the newly-invented nitro-compounds. Nor was this all. The torpedo system devised at Venice by the Austrian engineers had yet another point of scientific interest. A camera-obscura was built overlooking the harbour, and upon the white table of this instrument were reflected the waters of Venice. As the torpedoes were sunk one by one a sentinel in the camera noted the place of their disappearance with a pencil, giving each torpedo a consecutive number. A row boat in the harbour described a circle around the sunken torpedo indicating the zone of its destructive power, and the sentinel again, with his pencil, made a corresponding ring upon the camera table. In the end, therefore, while the harbour itself was apparently free from all obstruction, a very effective means of torpedo defence was established, the key of which was only to be found in the camera-obscura. The sentinel here had wire in connection with every torpedo, and was in a position to fire any one as soon as he observed—by means of the camera—the presence of a hostile vessel within the limits of any of the circles marked upon his white table.

"In the American war of 1860 the electric torpedo, invented but two years before, played a most conspicuous rôle, and formed, indeed, with the use of big guns and monitor ironclads, one of the most important features of the struggle, at any rate from a scientific point of view.

"The war of 1866, when the Austrians suffered such a terrible defeat at the hands of the Prussians, will long be remembered as a combat between the old muzzle-loading rifle and the breech-loader, in which the latter was victorious.

"The Franco-German struggle of 1870, again, though marked by the employment of no special arm, if we except the mitrailleuse, was assisted by important applications of science: to wit, the reproduction, by means of photo-lithography, of the French ordnance maps and plans, which were distributed in thousands throughout the German army, and the establishment in France of *la poste aerienne* to communicate with the besieged garrison of Paris. From September 23rd to January 28th, when Paris was practically cut off from the rest of the Republic, no less than sixty-four balloons left the city with passengers, mails, and pigeons, and of these only three were lost, while five were captured. The return post by 'homing pigeons'

was hardly so regular; but, nevertheless, half the number of dispatches given in by correspondents at Tours and elsewhere—or, in other words, one hundred-thousand messages—were, by the unflagging energy of the postal authorities, carried into the beleaguered capitol. The present Russo-Turkish war cannot well be less interesting than those that have so recently preceded it; and we may especially point out two directions in which fresh examples of scientific warfare will probably manifest themselves—in connection, namely, with the cavalry pioneer and the Whitehead torpedo. Both of these will probably be seen in warfare for the first time, and before many days are past we may hear of their doings in action. The cavalry pioneer must not be confounded with the Prussian Uhlán who played so conspicuous a part in the last war. The ubiquitous Uhlán, terrible as he was, did not work the injury which some of the Cossacks will have it in their power to inflict if accounted as pioneers. These are selected from the smartest and most daring troopers, lightly armed and well mounted. In a belt round their waists they carry a few pounds of gun-cotton or dynamite, and with this highly destructive explosive they may work incalculable harm. A small charge of gun-cotton, placed simply upon a rail, and fired with a fuse, suffices to blow several feet of the iron to a distance of many yards, thus rendering the railway unserviceable on the instant. A trooper may dismount, place a charge at the base of a telegraph pole, fire it, and be in his saddle again within sixty seconds. Wires may thus be cut and communication stopped in the heart of an enemy's country by fearless riders, who have but to draw rein for an instant to effect the mischief, while lines of railway in the neighbourhood are entirely at their mercy. Even light bridges and well-built stockades may be thrown down by the violent detonation of compressed gun-cotton, and forest roads considerably obstructed by trees thrown across, which are never so rapidly felled as when a small charge of this explosive is fired at their roots. The influence of the Whitehead torpedo, of which we have heard so much of late, will likewise be felt for the first time during the present war. An implement so ingenious in its character that, as Lord Charles Beresford the other day happily remarked, it can do almost anything but talk, is in the possession of both belligerents, and will doubtless be heard of before long on the Danube and in the Black Sea. These torpedoes are manufactured at Fiume on the Mediterranean, and, like Krupp guns, are to be purchased by any one who chooses to pay for them."

HINTS FOR CARBON WORKERS.

BY J. INGLIS.*

LONG, long ago, it appears to me, I promised to make you some negatives for your journal. When I promised to do so, I intended to fulfil the promise; but the fact of the matter is that I have been so troubled with those miserable chromotypes that I have had no time to take negatives for you, nor scarcely customers; fortunately there have been very few of them to trouble me all winter. So I have had a pretty good opportunity to work on the chromotypes, and with what results you will please judge for yourself from the samples I send you per this mail. I see, from your last number, you quote me as calling the process "simple simplicity." Well, it is; but I have been thinking a few times, nevertheless, as I have been trying to master this simple process, that I have been more like "simplicity" than it. However, since I have discovered where all my troubles lay, I will now reiterate the statement, with double force, that it is "simple simplicity." My first great mistake was in deviating from the rules laid down by Mr. Lambert. I am very much given to cut

a road for myself, and though I would not advise any chromotypist to do so at the beginning, I will say that I find a very great benefit from having done so. Of course the road was a hard one to travel, and I was very near backing out, and calling Lambert a humbug, and his process a bigger one. But just before giving up and confessing I was beat, I began to meet with success by degrees, and now, for these few weeks past, I have been getting into the simple, simple way of working it with great ease and pleasure.

To-day I found a gentleman standing looking at a case of chromotypes I have at the door on exhibition. "Mr. Ingles," he said, "I don't like this new style of picture."

"Why, that is strange, as every person seems to like them. Why don't you like them?" I asked him.

"They seem to stick out too much,"—motioning with his hand as if he would have pulled the likeness off the cards.

I think that critic's dislike will speak for itself.

Another case which is worth noticing for the sake of the fraternity who have not seen any chromotypes, but who have heard they are poor pictures, and not fit to be compared with silver prints:

A stock-dealer here, who has not the privilege of selling the Lambert patents, was very loud in his condemnation of the chromotypes—so much so that we had a few angry words over their merits and demerits. You may judge of my surprise on seeing my friend walking into my rooms a few days afterwards, and tendering me his congratulations on my success. In the meantime I had got a few of the pictures on exhibition at the door, and he had been attracted by their superior appearance, and, after examining them, he said he felt it to be his duty to come in and own up like a man that he was wrong in condemning them as he had done, and that he would now take back all he had said about them, as they were really a decided improvement on the silver prints; in fact, they were the best thing he had ever seen. When will our friend, the editor of the P. P., let the scales drop from his eyes? It is a fact that the silver prints are left clean behind, and it makes no matter who writes against the chromotypes: they are the pictures of the future, at least till they are outstripped by something we have not heard of yet.

For the good of carbon workers who may be troubled in any weather with their tissues drying too hard, I would recommend them to put it into a fuming box, and place a flat dish of hot water beneath it for ten or fifteen minutes, when they will find it as pliable as a piece of patent leather. Roll it up and put it in a tin box, when it will keep this way for a long time.

There has been a great deal said about mounting the chromotypes. Now, the best possible way to mount them is with gelatine. I have a tin pan which holds a gallon or so, which I keep always ready. When I want to use it, I heat a few minutes until re-dissolved; put it into a developing tray the size of the plates my pictures are on; soak the cardboards a few minutes, which are to be the same size as the whole of the pictures, on the glass; now, with a small sponge, rub over the back of the pictures a little of the gelatine; then lay on the cardboard, and, with a printer's hand-roller, roll out the surplus gelatine back into the tray, and with another sponge, and under the tap, wash off the gelatine from the back of the card and face of the glass; then squeeze the cardboard tight down, pile them all on top of each other, leave under pressure for an hour or so; then take and bind around the edge with strips of wood and spring clips, set them aside to dry, and when dry they will come off perfect and in full gloss. I prefer rolling them afterwards on a cold plate; not through a burnisher, but on a flat bedded roller. It gives them a very fine gloss, with a nice grainy appearance, and takes away a little hardness which glass pictures generally have, especially as I see them. I now cut them out upon a piece of lead, with dies round-

* St. Louis Practical Photographer.

cornered, the size of cartes and cabinets. With these same kind of dies I make my masks and tinters, at a cost of about five cents, instead of the Lambert frames at \$3.25 each, making a masker and tinter \$4.50, while mine is a great deal better every way for ten cents.

Instead of using the gelatine with the name printed on it, I have a rubber stamp, with which I print the name, &c., direct on to the glass, doing away with the troublesome medium of the gelatine. I have no doubt that after we get a year or so's practice at it we will have the process simplified to a much greater extent. Silver printers have no conception of the beauties of this process. I could take in hand to convert the most conservative in half an hour. Convince will suit better than convert, as many would prefer to tell a direct falsehood to admitting of their conversion.

Mr. D. G. Munger is not the first who has put a little piece of hypo into a silver bath my mistake, and found that instead of spoiling the bath, it happened to be one of the finest they used. A friend of mine here, a Mr. James Martin, made a similar blunder a few years ago. He was telling me of it last summer. I tried it, not by mistake, but intentionally, and found it clean the bath to perfection; and for a long time it worked as well as any bath I ever saw, but it finally gave out, and all the tinkering I could do I could not make it work again. I think I may have put in too much soda; but I would recommend any having a bath out of order to drop a small piece of hypo into it, and set it in the sun to purify, when they will find they have got a bath fit for making chromotype negatives.

Correspondence

PORTABLE PHOTOGRAPHIC STUDIO.

SIR,—I shall be glad if any of your readers will render me information as to the best method of constructing above, to allow of its being taken down and re-erected as often as required. A side and top approaching a high side light would be preferred, and of average size. Suggestions would be much esteemed. W. H. M.

To Correspondents

J. H.—A small portion of insoluble residue, which deposits at the bottom of the bottle, is not uncommon with good samples of pyroxyline. If the collodion work well, and the residue is small, the matter is not serious; but if there be a large portion insoluble, something is wrong. In the formula we gave, no water should be added to the acids; but it is important to maintain the temperature as high as we mentioned. A thermometer should be used to test this. Here is another formula which we have used with advantage:—

Sulphuric acid 1.840	12 fluid ounces
Nitric acid 1.450	12 "
Water	3½ "

When these are mixed, the temperature will rise; when it is about 140°, immerse the cotton as before described, taking care that it is quite dry, as the weakened acids will not admit of the admission of further moisture.

W. S. S.—Carbonate of soda, which is the common article known as washing soda, is a decidedly alkaline salt. The bicarbonate of soda, which is most commonly used in operations where delicacy and purity are of importance, is also an alkaline salt. In any decomposition of the latter, carbonic acid is liberated, and this has an acid reaction; but the salt as a whole cannot have an acid reaction.

R. MORRIS DAY.—We do not know the price of Henslik's work on photo-collotype printing. We do not know of any one selling or publishing it in this country. It is printed in German. Presumably a foreign bookseller, such as Traubner, would procure it, if ordered of him.

H. G. P.—In the Autotype Manual you will find very fully detailed instructions for either printing on canvas with carbon powder, or transferring on to canvas. Satisfactory instructions would more than fill the space we can devote to answers. A special tissue is desirable. The ordinary painting canvas is secured well with a solution of soda, and then coated with gelatine. The operation of transferring is then conducted in the usual way.

J. BULLOCK.—The result, which is very definitely marked, is due to unequal shrinkage of the paper. See leader on the subject.

B. L. J.—A common cause of thin images is the use of a collodion of insufficient body. Try if that is the case by coating a portion of a film twice. If that portion be more dense than the rest of the image, it will indicate that a thicker collodion will give you more vigour in your negatives. Add, in that case, one grain per ounce of pyroxyline to the collodion. Sometimes a thin image is the result of the mode of applying the developer. If you dash it on the plate, so that it drives off all the free silver solution, your image will be thin, from want of deposited silver. Apply the developer gently, so as not to displace the silver solution on the plate. Avoid using the iron solution too strong. See, also, that the object is well illuminated.

D. W.—The streaks on the piece of negative forwarded are due to floating scum in the negative bath. Before commencing work, draw a strip of clean blotting paper over the surface of the bath until it is quite free from scum or greasy-looking patches floating on the surface. 2. The brown tone of the enclosed print is chiefly due to the use of a weak negative, which does not permit the blacks to be printed deep enough without over-printing the face. It is almost impossible to get rich tones in prints produced from such negatives. Vigour in the negative is an important element in securing a rich black tone in the print.

H.—You will find it more satisfactory to use hydrochloric acid than salt in precipitating the silver in your washing water. Take care to avoid adding unnecessary water, as the more dilute the solution is made, the slower and more troublesome the precipitation. The proportion of acid depends entirely on the silver present; but scum will do no harm. For every quart of washing water add five or six drops of acid. The question whether you should reduce the chloride and other residues yourself, or send to a refiner, is one of economy. If you have facilities, experience, and time, you will undoubtedly save something by doing it yourself. But in the majority of cases it is wiser to send to a refiner.

MAX.—You will ascertain full particulars on application to the Autotype Company.

WOULD-BE-CONTRIBUTOR.—An exhibition will be held, and medals offered; no details beyond this are decided.

LUX.—An ordinary sitting room with a bay-window about eight feet across will, used with skill and care, permit of the production of very fair portraits. Place the sitter about three or four feet from one end of the window, sitting on a chair slightly inclining to the window, with the head slightly turned from it. Place a white screen or a clothes-horse with a white sheet over it directly opposite to the window, and inclined in such position as will illuminate the shadowed side of the head with reflected light. We have seen very excellent portraits produced with such a light.

CONSTANT SUBSCRIBER.—The cause of the absence of richness in the tone of your print is not in the gold bath, or in the exciting bath, but in the negative, which lacks vigour and intensity. The tone of the print enclosed is indeed very good for a print from a somewhat weak negative. Unless you have sufficient force and intensity in the negative to permit the shadows to be printed very deep without over-printing the face, you will fall in securing that richness you desire. Try printing in the shade with your present negatives. That will improve matters a little.

A CONTINENTAL SUBSCRIBER is anxious to obtain photographic lantern slides of Staffa, Fingal's Cave, Giant's Causeway, and other geological subjects, also moveable astronomical subjects for demonstration purposes. Can any of our readers help him?

A CARELESS READER, who does not file his NEWS carefully, asks us to search out and repeat for him various formulae. We are always anxious to oblige our readers; but we regret that the pressure of our ordinary duties does not leave us time to save our correspondent the ordinary and legitimate care which he himself should exercise.

J. FRANKMAN.—Your photograph was registered on April 18th. The mention of photographs registered is often delayed when we are pressed for space.

Several Correspondents in our next.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

THE CAMERA AT THE WAR—THE IMPORTANCE OF A KNOWLEDGE OF LITHOGRAPHY IN LIGHT-DRUCK—THE BEHAVIOUR OF IODIDE OF POTASSIUM IN SUNLIGHT.

The Camera at the War.—At last special correspondents have begun to think of employing photography to help them in their arduous work. Why they have not done so before we cannot tell, for dry plates are not things of yesterday, and the camera, although it may not at times be able to replace the nimble pencil of the draughtsman, frequently gives results which are simply unattainable in any other way. Now, too, that we are possessed of a material like the Warnerke film, and there is no need of development on the spot, photography is especially suited for campaigning, and we wonder that more application has not been made of the art. Some weeks ago a very good example of what photography can do in a parallel case was afforded at a meeting of the Photographic Society. A series of negatives were shown, taken in North Africa near Cairo, which the photographer had not himself beheld. He had gone on his journey with a camera and a roll of sensitive tissue, and when he had exposed a score of times and had come to the end of his roll, he simply took it out of the dark slide and posted it to London, where the pictures were developed. It seems to us that war correspondents connected with illustrated papers would do well to adopt a similar *modus operandi*, and no doubt if they were only aware how easily pictures are taken now-a-days they would feel little hesitation in the matter. Mr. Alderman Nottage, of the Stereoscopic Company, who has resolved to despatch a correspondent to the battlefields of the East, has just adopted the roller dark slide for the equipment. Acting on the advice of Mr. Baden Pritchard, of Woolwich, who both as an amateur and one who has paid much attention to light equipment for reconnoitring purposes, Mr. Pocock, an officer of the London Stereoscopic Company, has been provided with the ingenious roller slide devised by M. Warnerke, and with that gentleman's tissue; he has already started on his journey, and without troubling himself in any way with the development of his pictures, will simply forward batch after batch as he takes them. A more simple arrangement can hardly be conceived, and as but few precautions are necessary to secure successful impressions, we may hope to see the energetic establishment of which Mr. Alderman Nottage is the chief publishing war photographs in a little while. It is very singular, in fact, that a very few war photographs have been published. Of the Franco-German battlefields we hardly remember seeing a single instance. A series of pictures were taken of Strasburg, during and after its investment, and also of Paris by the German staff of photographers, but those did not include any of the famous battlefields of the war. Photographs of the barricades thrown up by the Communists in Paris we have also seen, these pictures having a melancholy interest, since the portraits of officers and soldiers included in the photographs served afterwards for their conviction. But beyond a dozen prints of this kind, nothing of a photographic nature remains behind to tell the story of that significant war. On the other hand, of the China war of 1860 there are several battlefield photographs extant, pictures which at once bring home to the spectator the reality of a war. Of Abyssinia also there are some capital pictures extant, illustrating that laborious march of four hundred miles over a pass eight thousand feet above the level of the sea, and showing us exactly what the stronghold of King Theodore was like, as well as the nature of the native architecture, the churches, &c. Even of the Crimea we have some taking photographs—of the Redan, for instance, its state of destruction showing but too well how terrible was the struggle for its possession.

There cannot be a doubt, we think, that a series of photographs illustrating the battlefields of the East would be attractive just now, for if the public look at woodcuts and engravings, they will be sure to feel a desire to see veritable photographs taken on the spot.

The Importance of a Knowledge of Lithography in Licht-druck.—We have placed before our readers the most important points connected with Husnik's improved Licht-druck process, and we have shown that he places particular stress upon one innovation, namely, the use of soluble silicate. But one cannot help remarking that much importance is attached to good printing when it comes to using the press, and this leads us to remark once more upon the advisability of all photographers having a skilled lithographer to help them in carrying out a process of this kind. Lithographic printing is an art not learnt in a day, and if to be a collotype printer one must needs understand lithography, it is obviously of little good for a photographer to attempt the production of Lichtdruck prints without any knowledge of printing from stone first of all. Some years ago an illustration of this came under our notice. A well-practised photographer desired to take up the art of photo-lithography, and attained to some success as far as producing the transfer went, but somehow or other he never got any further. Either he produced a photo-transfer in which the image contained too much ink, and consequently got crushed on being transferred to stone, or there was not sufficient transfer ink, and then the image upon the stone failed in places. It never occurred to him that skill and experience of another kind entered into the matter, and he was considerably surprised when an ordinary lithographer was able to take up the matter where he left it, and to produce very good impressions. With a delicate process like Lichtdruck, the necessity for having a skilled printer is more marked still, and it would be contending with insuperable difficulties for anyone unacquainted with litho or zinco-graphic printing to attempt the production of fine Lichtdrucks. So much depends upon skilful printing, and in being able to resort to this or that expedient, that, as Husnik points out, success can hardly be acquired by one unskilled in surface printing. This will not, we hope, deter photographers in this country from attempting the charming process, for it is in this direction that progress in photo-mechanical printing undoubtedly lies. Lithographic printers are easily found, and their work is of a class that is not highly remunerated. Moreover, a few days or weeks spent under the tutorship of a good lithographer are very profitably spent, for now-a-days it behoves the photographer to know something of an art which is so closely allied to his own.

The Behaviour of Iodide of Potassium in Sunlight.—That iodide of potassium in solution changes its colour on exposure to daylight is a fact which many chemists have already noted. A French chemist, M. Vidau, in some experiments recently made upon the subject, has proved that the change is not due to light alone, but that the gases of the atmosphere have a decided influence in the matter. If a solution of iodide of potassium is exposed under ordinary circumstances to air and sunlight, the liquid rapidly becomes yellow, and, after a short time, is found to contain free iodine. But this is not the case if (a) the air is cut off, or (b) the sunlight is cut off. The solution exposed to sunlight in a vacuum undergoes no change, neither does it if exposed to air in the shade. M. Vidau concludes that sunlight and the acids of the air, and more especially carbonic acid, are the principal causes of the change, for he found that when a solution of the compound was exposed to sunlight in the presence of carbonic acid, decomposition went on far more rapidly than was the case when ordinary atmospheric air was present. A solution of iodide of potassium exposed to the action of sunlight and carbonic acid rapidly gave off free iodine; and

in two hours the solution was quite yellow, and gradually became darker. As iodide of potassium is a compound with which photographers constantly have to do, it is well to note its behaviour under the circumstances described.

A NEW FORM OF MEGASCOPE.

BY J. B. KNIGHT.*

THE projection on the screen of the images of small opaque objects is often a very desirable means of illustrating lectures or papers read before societies, but has not been very largely employed, because of some difficulties attending its use.

As the light for forming the image is only that emanating or reflected from the surface of the object, it is important that it be strongly illuminated. The arrangement about to be described was devised to secure a better illumination than is obtained with the ordinary megascope, and at the same time save the cost of a special instrument, by utilizing the ordinary projecting lantern with which nearly all our educational institutions are provided.

The arrangement for accomplishing this purpose is shown in the accompanying cut, in which A represents the lantern box, B the lime, C the oxyhydrogen gas jet, and D, the condenser—all of the ordinary constituents. F represents a tube of sheet metal, of the proper size to fit snugly over the ring of the condenser, and of sufficient length to reach considerably beyond the focus of the beam of light from it. The object I is held, by the stage G,

in the beam of light, as near its focus as possible, and yet give the proper breadth of illumination. This stage G is supported by and hinged across its centre to the inner movable tube R. To the tube F is attached a branch for holding the focusing lens at the proper distance from the illuminated side of the object, with its axis at as small an angle from the axis of the condenser as will permit the cone of light passing from it to the screen to clear the top or sides of the lantern box. Objects are easily placed on the stage G by withdrawing the inner tube R, and are easily adjusted by this longitudinal movement and the angular movement of the stage on its hinges.

This attachment is simple and inexpensive, and by it the usefulness of the projecting lantern is greatly increased.

A PRACTICAL SUGGESTION.

BY W. E. HOSKEN.†

BETTER work is, I presume, what we are all striving to make, and doubtless are looking for help in that direction from *The Practical Photographer*. I, as one anxious to improve, should like to suggest a direction in which I think information is needed.

In looking through my collection of photographic literature (and I have copies of most that has been published), one is struck with the change that has taken place in the class of information given in the earlier and later works; in the one, it is all formula, page after page devoted to

developers, intensifiers, collodions, &c. Now, we get more suggestions how to use the formula we have, and more of art as applicable to photography. This evidently shows the direction of the thinkers among us who practice our art. I do not wish to decry the value of formulas; they are essential, especially so in all that pertains to new discoveries and improvements; but the day has gone by when we should look for the reason that A makes better pictures than B among A's pet formula. Such men as Kurtz, Sarony, and others of equal ability have given their formulas to the world, and we find them using the same as ourselves; but the results, how different! Elbert Anderson, in his work, very properly suggests the use of a chemical known as brains to mix with his formula; the advice is good, but would not be well, too, if such men could be induced to give us dilutions of their brain power, so that they might leaven us in practical suggestions adapted to every day work? Little matters, which are probably regarded as not of sufficient importance to be worth recording, go to make up that perfection which exceeds our own. Do chemicals mixed with brains ever get out of order, and refuse to yield perfect results? I presume they do, and then comes the addition of more brains, and lo! all is well. Yes, but it might be interesting and very beneficial to some of us to read a carefully written description of the difficulty (minute even to tediousness were better than so slight as to be unrecognizable) and how it was gotten rid of; by all means let us know how the demon was exorcised, for in that your *Practical Photographer* is most interested. Such men need fear no loss of reputation because of owning that things are not always well with them, especially when that oft-mentioned chemical has removed the trouble. Then, again, many of us, who do not pretend to be teachers, doubtless get into difficulties the learned never encounter, although they may have done so in years gone by. What better place to describe them than in our *Practical Photographer*—and get the benefit of others' brains to help us solve the problem, besides leaving them on record as a guide post to warn the unwary in the future?

Now, so as not to leave myself open to the charge of advising others to do what I myself fail in, I will describe a trouble I have met with lately, and only got rid of by discarding the bath I was using, and making a new one; and this is a rare occurrence with me, so rare that I can hardly ever tell how many years it is since I made the last, that is, wholly new—as I generally work it over when it gets out of order, add new silver to bring it up to the requisite strength, and go on satisfactorily. This particular bath has been served so a great many times. Some time ago the plates from the bath showed it to be greatly reduced in strength, although working clear (for fogging is a thing I am not troubled with, although I have encountered that enemy in times past to my heart's content). I removed it from service, and put it through the usual course of doctoring; neutralized, precipitated part of the iodide, boiled it to evaporate alcohol and ether, strengthened it with fresh silver, filtered, made it slightly acid with nitric acid, and they soon set it to work again. It worked clear as usual, but there seemed a disposition to form streaks and fine lines in the film. To me they were of an unusual character, not at all like streaks usually spoken of as "streaks in the direction of the dip" from bath and collodion not being in harmony, still following generally in the direction the plate was immersed; but they were fine transparent lines, seldom reaching clear across the plate, but commencing near the edge and reaching to the centre, and sometimes two-thirds of the way across, while sometimes others passed in from the other side; at times they formed a sort of ribbon mark, two fine transparent lines running nearly parallel to each other about an eighth to three-sixteenths of an inch apart, while between them the film was thinner than surrounding parts; occasionally the Old Nick seemed to pay in some one plate, and then we got a lovely result—fine lines and ribbons, and short ends

* *Journal of the Franklin Institute.*
† *Practical Photographer.*

of the ribbon marks crossing the others at different angles, forming a complete maze.

I will try to give an idea of the markings here in two cases, and if our editor is a genius with his pocket knife, he may furnish us a woodcut. You will observe, if my markings are reproduced, that there is another feature I have not yet mentioned, that is, innumerable small rings, the outside line semi-transparent, the inside like the ribbon marks, somewhat thinner than surroundings. At first I looked for the fault in my collodion, as my baths almost invariably work well until exhausted by loss of silver, and the collodion was a fresh supply; but changes in that direction did not work any improvement, so I made a new bath to take its place, and, "presto change," the enemy had vanished, root and branch—not a trace of it to be found. This trouble was not as bad at first as here represented, but kept growing worse; when I removed the bath, the hydrometer indicated thirty grains of silver to the ounce. Now, this may be a common and well understood difficulty to many, and if so I congratulate them on their acquaintance; but for my part, in the thirteen years I have followed the business for myself, I have never met the gentleman before, and do not wish to again, nor do I find it described in any photographic work or journal. I shall simply state a suspicion I have of the cause of the trouble. When I removed the bath, I found that the rubber dipper, which I had been using in it, was very much corroded. Before using it in the new bath, I thoroughly scraped it, and then varnished it with shellac varnish. Now, it may not have had any influence, but I am inclined to attribute to that corroded material of the rubber dipper, acting upon the film while in the bath, the cause of the trouble. In explanation, I must state that I dip a plate differently from many, always coating a plate with the film side in towards the dipper. These I prepare by warming and bending into a curve, so that the bottom and top edges of the plate only rest against them. I find (generally) in this mode of dipping a great immunity from specks and pinholes. If the editor does not consign this to the waste-basket, I should like to read the opinions of others on the trouble.

HUSNIK'S IMPROVED LICHTDRUCK.*

In order to produce Lichtdruck prints of the same tint as photographs there should be added to the lamp black some red varnish and carmine. These colours, however, change very soon, and the Lichtdruck, which is deemed so permanent, does not preserve its tone or beauty for a year. If the confidence of the public is to be secured, it will be necessary to exercise judicious care in the selection of suitable pigments. Fortunately these exist, and are easily obtained. Instead of the costly varnish, the dark violet, called *caput mortuum*, which is by no means expensive, costing but fourteen florins for two hundred pounds, may be employed and mixed with the finest black printing ink. This mixture gives very fine and perfectly permanent prints, which leave nothing to be desired. The best description of printing ink is sold in canisters of various sizes, the smallest being a pound canister costing from three to four florins. The colour is very fast, and may therefore be employed mixed with varnish, or as it is. It is at once to be distinguished from other inks, since it possesses a very black tone, and a yellow metallic lustre like Indian ink. Other black inks appear grey beside it. The genuine ink goes a long way, and gives deep blacks even when employed in a dilute form.

For Lichtdruck printing any paper almost may be used, sized or unsized, and with or without a facing of chalk; it may be any thickness, and should be chosen according to the nature of the work to be performed. Pictures on a large scale with broad details, or such as are to be employed as diagrams, or for instructional or scientific

purposes, should be printed upon good sized paper of considerable thickness. The impressions, as they come out of the press, are finished, and require no further treatment. They have the appearance of photographs printed upon salted or arrowroot paper. Prints having very fine or microscopic details, on the other hand, should be printed upon paper with a facing of chalk, which has a beautiful matt glaze, and furnishes prints that may compare with albumenized pictures. Papers which have no facing of chalk are printed in a moist condition, but no damping is applied to a chalk surface unless it has been sized.

The prints have a tendency to stick to the gelatine block, especially in the high lights, but this defect is at once avoided by using moistened paper. The paper, when wet, does not absorb moisture from the gelatine surface, and consequently never sticks. Using glycerine and water, instead of water, for moistening the paper, is an infallible remedy, and in summer especially is to be recommended.

The roller process formerly employed by Albert for Lichtdruck printing is now replaced by the ordinary lithographic press, which acts with a scraper. The most approved methods of lithographic printing are therefore applicable to the production of Lichtdrucks, the operator always bearing in mind that he has a more delicate material to deal with than the litho. stone. He should therefore adopt every precaution that is taken in delicate work in reference to pressure exerted, &c. Lithographic presses should be arranged for Lichtdruck printing, however, since there is a considerable difference in the two processes.

In printing from a lithographic stone, for instance, the paper must be energetically pressed against the printing surface, so that every portion of the paper may be forced into contact with the hard surface, and take up all the ink.

In printing from a gelatine surface it is different. In this case the block is soft and elastic, and comes halfway towards the paper; a slight pressure with the finger suffices, indeed, to ensure the paper taking up the ink from the gelatine surface. The ink, too, has a natural tendency to leave the wet gelatine surface, and this is one reason the more why very little pressure is necessary in Lichtdruck printing.

In order to protect the elastic gelatine block as much as possible, and to avoid pressing and maltreating it more than is necessary, special printing presses have been constructed, in which the pressure can be regulated by the hand with the greatest nicety. The scraper may be made of a far less solid nature than in the case of the ordinary litho. press, and in this way any unevenness in the glass or in the bed is not felt. Breaking of the glass and injury to the film are accidents which never occur in a well ordered and adapted press, and it is immaterial whether the glass plates employed are thick or thin. As, however, a thin plate is not so strong, and is not so easily submitted to the process of graining or polishing, it will be found advisable to make use, as a general rule, of plates of appreciable thickness.

Like the glazing of a photograph, the varnishing of a Lichtdruck is done simply to gratify the public taste. It is a weakness, but one which has frequently to be indulged if the Lichtdruck is to compete with the ordinary photograph for general favour. The print must be first of all covered with a gelatine solution before it is varnished. There are several stable varnishes in commerce, such as shellac, mastic, &c., which consist of gum resins dissolved in alcohol. After coating with or immersing in gelatine solution, the Lichtdruck is dried, and the varnish then applied, this being first of all mixed with some spirits of wine in order to take to the greasy image better, and also to avoid the formation of air-bubbles.

According to my experience, two parts of white shellac and one part of gum mastic dissolved in absolute alcohol give a suitable and inexpensive varnish for the purpose.

The varnishing must, however, be undertaken near a stove or fire, to prevent the film assuming a turbid, opaque character.

A very good suggestion as to the varnishing of Lichtdruck pictures has emanated from M. Martin, one of the members of the Vienna Photographic Society. That gentleman proposes the production of two gelatine printing blocks from every negative, and applying ink to one block and varnish to the other. Two printings are, as it were, required, a sheet of paper being first impressed with an image, which is afterwards varnished in the second press. This method of operating is quicker than varnishing each print by hand, but it has, moreover, another advantage: the high lights of the picture are not varnished at all, while the shadows have varnish applied in proportion to their intensity. The whites, being unvarnished, have no yellowish tint, and, consequently, appear fresher to the eye.

By adopting this method of varnishing, it would be possible to employ a thick turpentine varnish, which would have the effect of making the colour adhere more firmly to the paper; at the same time the margins would be preserved in their clean, untouched condition.

As regards retouching, it is recommended to do all that is possible upon the negative itself. If, however, any writing is required upon the gelatine block, then this may be done with a pigment to which a solution of tannin in water has been added. Lines, dots, or other marks made upon the gelatine block with this mixture of tannin will be printed off afterwards. The retouching may also be done by the aid of bichromate of potash solution.

[In another article, we propose to give a summary of the manipulations and defects incident to Lichtdruck.—Ed. P. N.]

BINOCULAR VISION EXPERIMENTS.

BY FRANCIS E. NIPHER.

It is possible that the phenomena here described may have been observed before, but I have been unable to find any record of them.

1. Fold a sheet of writing-paper into a tube about an inch in diameter. Look through the tube at some distant object with one eye, and toward the open hand with the other eye, the edge of the hand being in contact with the tube. The dissimilar objects producing unlike images upon the retinae, the sensations blend, and a hole will appear to be cut through the palm of the hand, through which the tube passes. That part of the tube between the eye and hand will appear to be transparent, as though the hand was seen through it. This experiment is very old, but seems not to have found its way into scientific literature.

2. Replace the hand by a sheet of unruled paper, upon which a drop of ink has been placed. By proper management, the ink blot may be made to appear within the tube, by so placing the paper that the hole, which is apparently cut through it, coincides with the blot. Ordinarily the blot will then appear opaque, the paper immediately around it, and apparently within the tube, being invisible. The blot appears, as it were, suspended in space. By concentrating the attention strongly on objects seen through the tube, especially if they are strongly illuminated, the blot becomes more hazy, transparent, and may even be made to disappear altogether. The mental effort necessary to do this cannot be maintained more than a few seconds, and the spot will re-appear. If the effort to cause the spot to thus disappear be kept up, the attention being strained to its highest pitch, the blot will disappear and re-appear at regular intervals of a few seconds, the absolute time depending upon the illumination. It seems as though the organs exerted become fatigued, and, relaxing for a few moments, refreshment sets in, which again renders possible the exertion necessary in causing the blot to disappear. It is possible that these experiments may be so made as to throw some light upon the conditions necessary in fixing the attention.

Interesting experiments may also be made by substituting a fragment of a plane mirror for the sheet of paper. Looking through a rather large tube at a distant object with the right eye, the reflected image of the left eye will appear staring up the tube, the adjoining parts of the head being invisible.

3. Substituting for the ink blot a small hole cut through the paper, the small hole can also be made to appear within the tube, distinguishing itself by its different illumination, the surrounding paper being invisible, unless attention be directed too strongly to the paper in which the hole is cut. The relative illumination of the small hole, and the space immediately around it, depends upon the relative illumination of objects upon which the tube is directed, and that of the sheet of paper exposed to the other eye.

4. Keeping the same arrangement, place at a distance of one foot from the end of the tube a sheet of paper, so that objects beyond it are still visible; arrange matters so that it is visible to the eye looking through the tube, but not to the other directed at the small hole in the paper sheet. This second sheet will now appear to be traversed by a hole the same in size as that cut through sheet No. 1.

Cutting a small hole in sheet No. 2, matters are easily arranged so that it appears within the hole which was before seen within the tube. These experiments may be utilized in showing the simultaneous accommodation of the two eyes.

5. Tubes of this kind, blackened on the inside, are very convenient in studying colour sensations. Using two such tubes, look through one with the right eye (say) at red, through the other with the left eye at green paper, illuminated by the direct solar ray. The colour sensations fade with marvellous quickness. Transferring both eyes to either colour (say red), the eye, fatigued by green, sees the red greatly intensified, the effect being rendered the more striking by the simultaneous impressions received by the two eyes. Experiments in the combination of colour sensations will readily suggest themselves.—*American Journal of Science.*

LANDSCAPE AND ARCHITECTURAL PHOTOGRAPHY.

BY S. R. STODDARD.*

I HAVE often felt that "instructions for beginners" were of a nature only to be understood after the point was reached where beginners could do without the instructions, and if it displays a lack of scientific accomplishments to make the acknowledgment, I must still say that I write my formulae in the commonest kind of English, and aim to simplify the work to the extreme of simplicity.

The Glass is cut the required size, and allowed to remain in pickle (one quart sulphuric acid to one gallon water) for two or three days, then washed under a tap, albumenized, (solution: white of an egg to about twenty-four ounces water), and set on edge in a rack to dry. When dry it is marked in one corner with india-ink, to show which side is coated, done up in dozens, wrapped in two thicknesses of paper, and securely pasted to keep free from dust, then stored away for future use.

The Bath is made up to test, forty-five grains of silver to the ounce of water, enough collodion added to cover the largest plate used in the given quantity of solution, and all placed in the sun to purify. When clear, filter and use.

Collodion.

Alcohol	10 ounces
Ether	10 "
Iodide of ammonium	100 grains
Bromide of cadmium	20 "
Gum-cotton	about 100 "

(I usually keep on hand one or two kinds of standard collodion, to use in case mine fails to work).

Lenses.—I usually carry four pairs, varying from two and

a half to ten inches focal length, for stereoscopic work, and a ten-inch Morrison for single views, each fastened on its separate front, fitted to my camera, and all contained in a light wooden box with space for each. This box I carry in my hand to each point of view, and select lenses to suit the subject, invariably choosing the longest-focussed instrument that can be used in the prescribed limits, as wide angles fill the foreground with unimportant objects, and dwarf stately mountains down to insignificant lines.

For Landscapes I prefer single (achromatic) lenses, as the slight curvature at the margin is ordinarily of no account, and more than compensated for by the greater sharpness and detail obtained. They are also (when perfectly clean) free from a trouble which sometimes goes with the very best of combination lenses, a centralization of light, and a fuzziness at the edges where a dark object is brought against a strong light. Some of my best work has been produced with a pair of object-glasses taken from an ordinary opera glass (three-inch focus), mounted in rigid settings, and properly diaphragmed in front.

For Architectural Work something better is needed, and found in the "Morrison" and "Dallmeyer" wide-angle rectilinear lenses, which take in an angle of nearly a hundred degrees; they are expensive, but invaluable and perfect in their way. In my mind, there is little choice between them; and an outfit would be incomplete without a pair of either one kind or the other, two and a-half inch focus for confined situations, interiors, or mountain gorges and waterfalls, such as I have often found among the Adirondacks. Of course, the rule requiring as long a focussed instrument as possible holds good, and applies with even greater force to architectural subjects; but this smaller kind of lens is often necessary for field work simply because a single lens cannot be found of sufficiently wide angle.

For Instantaneous Work a pair of portrait tubes, thirds or quarters, are best. I have used a pair, four-inch focus, manufactured for the trade under various names, but called by Benjamin French and Co., of Boston, their "new stereoscopic lenses, imitation Dallmeyer." They are good for groups, heads, &c.

Tripod.—For light work I made a tripod of ash, four and a-half feet long, turned in a lathe, one and five-eighths inches thick at its largest, and tapering gradually from centre to bottom. It was then split in six pieces with a fine saw. The pieces, when smoothed and bound in pairs about half way up, formed a round bundle, which, fitted with a light top of the ordinary viewing pattern, is nearly as firm as the clumsier article, and, when folded, but little heavier than a large cane.

For Travelling by rail, I have two small trunks, padded for chemicals, glass, &c. The dark-box we can carry in one hand, or, if necessary to put in the baggage car, I find that a silver half or quarter dollar laid on top of the box is a much better protection than rubber corners.

For going about the country, I have a roomy carriage, for one horse, with top (the carriage, not the horse), and rubber blanket, fitted over the dasher, coming in front nearly up to a level with the eyes. One, also, from the seat extends back over the ample body, where everything can be kept dry and secure even in the severest storms.

The Dark-box is secured at the back end, resting on a light iron frame or boot similar to those on the rear of stages. When driving, the box is closed and carried upright. When work is to be done, a strap is loosened; a part drops over back at a proper height to be worked handily from the ground, the top is extended, and we are ready for work. The same box can be taken from the carriage by simply loosening a nut. It has solid legs (two of them regulated by set screws, as I do not like the tripod arrangement for the dark-box—it's tempting providence too far), and straps for the shoulders, by which it can be easily carried.

Assistants.—I do not attempt to work alone; have found that the hours of suitable weather in the course of the year were too few to waste; and, of course, all work done under other than favourable conditions is a clear loss. I attend

simply to the camera, carefully selecting points, and making all exposures. The dark-box is in charge of Charles Oblenis, who has been with me several years, and to whose skill and careful manipulation is due no small share of what you have been pleased to compliment in the results obtained.

Arrived at the place to be covered, I secure the services of some boy—sometimes two—choosing one who looks as though he was wide awake, and with an extra inducement for quick time, set him to running with plate-holders between the camera and dark-box. You who have climbed hills or "scooted" across fields under a hot sun, to make a distant exposure, perhaps to find your tripod upset by a passing breeze, and returned with the plate to plunge your head into what, in your then condition of blood, seemed as hot as an oven, and about as dark to your contracted pupils, and in the end spoil the negative in consequence of your unstrung nerves, will bless and appreciate that boy; and when the work is done, and you look at that boy, covered with dust, and perspiration, and glory and silver, you cannot refuse him good pay for his day's work, and your own work will be better, too, for you have kept a clear, cool head at your work all the time. We use three or four plateholders; they often passing each other on the way to or from the camera, and where long exposures are necessary, one is often prepared and ready to be exposed immediately the other is taken away. After developing (one ounce protosulphate of iron, pint of water, and acetic acid to make it flow easily), the negative is flowed with—

Preservative, composed of two ounces glycerine, four ounces acetic acid, and ten ounces water, and placed in a negative box to await further action. This

Negative box is made of sheet copper, nine inches high, six inches one way, and deep enough the other to allow five by eight negatives to slide easily in separate grooves, made of strips or troughs of copper soldered fast, and affording space for thirty-two negatives. When through with the day's work, or sooner if necessary, the negatives are removed, washed, fixed (I use cyanide), washed again, and placed in the ordinary wooden negative box. I place a strip of wood across the bottom of the copper box to lift the negative above any of the preservative that may gather there, and guard against a possible stain. The cover shuts over the upper edge, and is lined with rubber to make it tight, fastened with a hasp and wooden pin. In this manner they may be kept several days without drying, and the necessity of carrying water is entirely done away with.

Redeveloper.—If weak, I place the negative (at any time after it is dry, and in daylight) back in the bath for a few seconds, then redevelop with ordinary iron developer, about one-half the usual strength, adding a little more acetic acid if it crawls when poured on.

After varnishing, I cut my stereo negatives, and fasten on other glass at the edges with gummed paper, placing the right-hand picture on the left side, to save the trouble of transposing the prints in mounting.

The Names.—Secure fine writing paper (the kind known as "onion skin" I have found best), have the names printed with the best of black ink, and all the type will bear without filling up (and, by the way, the type should be new and clean, at least not worn round the edges); let this get thoroughly dry, then cut out close to the letter, lay on the negative face down where it is designed to go, and, with a small brush, apply at the edge some kind of adhesive medium which will flow readily under the paper, make it transparent, and at the same time not disturb the surface of the negative or of the letter. I have found diamond varnish the best thing so far.

The negatives I keep in long grooved boxes, set up one on the other like shelves. Each negative is numbered from one up, and has its corresponding place in the box. I have a large book containing the views arranged in numerical order (extremely handy to select from and in making out printing lists), and large cupboards with pigeon-holes arranged in the same way to contain the finished pictures.

The varnishing must, however, be undertaken near a stove or fire, to prevent the film assuming a turbid, opaque character.

A very good suggestion as to the varnishing of Lichtdruck pictures has emanated from M. Martin, one of the members of the Vienna Photographic Society. That gentleman proposes the production of two gelatine printing blocks from every negative, and applying ink to one block and varnish to the other. Two printings are, as it were, required, a sheet of paper being first impressed with an image, which is afterwards varnished in the second press. This method of operating is quicker than varnishing each print by hand, but it has, moreover, another advantage: the high lights of the picture are not varnished at all, while the shadows have varnish applied in proportion to their intensity. The whites, being unvarnished, have no yellowish tint, and, consequently, appear fresher to the eye.

By adopting this method of varnishing, it would be possible to employ a thick turpentine varnish, which would have the effect of making the colour adhere more firmly to the paper; at the same time the margins would be preserved in their clean, untouched condition.

As regards retouching, it is recommended to do all that is possible upon the negative itself. If, however, any writing is required upon the gelatine block, then this may be done with a pigment to which a solution of tannin in water has been added. Lines, dots, or other marks made upon the gelatine block with this mixture of tannin will be printed off afterwards. The retouching may also be done by the aid of bichromate of potash solution.

[In another article, we propose to give a summary of the manipulations and defects incident to Lichtdruck.—Ed. P. N.]

BINOCULAR VISION EXPERIMENTS.

BY FRANCIS E. NIPHER.

It is possible that the phenomena here described may have been observed before, but I have been unable to find any record of them.

1. Fold a sheet of writing-paper into a tube about an inch in diameter. Look through the tube at some distant object with one eye, and toward the open hand with the other eye, the edge of the hand being in contact with the tube. The dissimilar objects producing unlike images upon the retinae, the sensations blend, and a hole will appear to be cut through the palm of the hand, through which the tube passes. That part of the tube between the eye and hand will appear to be transparent, as though the hand was seen through it. This experiment is very old, but seems not to have found its way into scientific literature.

2. Replace the hand by a sheet of unruled paper, upon which a drop of ink has been placed. By proper management, the ink blot may be made to appear within the tube, by so placing the paper that the hole, which is apparently cut through it, coincides with the blot. Ordinarily the blot will then appear opaque, the paper immediately around it, and apparently within the tube, being invisible. The blot appears, as it were, suspended in space. By concentrating the attention strongly on objects seen through the tube, especially if they are strongly illuminated, the blot becomes more hazy, transparent, and may even be made to disappear altogether. The mental effort necessary to do this cannot be maintained more than a few seconds, and the spot will re-appear. If the effort to cause the spot to thus disappear be kept up, the attention being strained to its highest pitch, the blot will disappear and re-appear at regular intervals of a few seconds, the absolute time depending upon the illumination. It seems as though the organs exerted become fatigued, and, relaxing for a few moments, refreshment sets in, which again renders possible the exertion necessary in causing the blot to disappear. It is possible that these experiments may be so made as to throw some light upon the conditions necessary in fixing the attention.

Interesting experiments may also be made by substituting a fragment of a plane mirror for the sheet of paper. Looking through a rather large tube at a distant object with the right eye, the reflected image of the left eye will appear staring up the tube, the adjoining parts of the head being invisible.

3. Substituting for the ink blot a small hole cut through the paper, the small hole can also be made to appear within the tube, distinguishing itself by its different illumination, the surrounding paper being invisible, unless attention be directed too strongly to the paper in which the hole is cut. The relative illumination of the small hole, and the space immediately around it, depends upon the relative illumination of objects upon which the tube is directed, and that of the sheet of paper exposed to the other eye.

4. Keeping the same arrangement, place at a distance of one foot from the end of the tube a sheet of paper, so that objects beyond it are still visible; arrange matters so that it is visible to the eye looking through the tube, but not to the other directed at the small hole in the paper sheet. This second sheet will now appear to be traversed by a hole the same in size as that cut through sheet No. 1.

Cutting a small hole in sheet No. 2, matters are easily arranged so that it appears within the hole which was before seen within the tube. These experiments may be utilized in showing the simultaneous accommodation of the two eyes.

5. Tubes of this kind, blackened on the inside, are very convenient in studying colour sensations. Using two such tubes, look through one with the right eye (say) at red, through the other with the left eye at green paper, illuminated by the direct solar ray. The colour sensations fade with marvellous quickness. Transferring both eyes to either colour (say red), the eye, fatigued by green, sees the red greatly intensified, the effect being rendered the more striking by the simultaneous impressions received by the two eyes. Experiments in the combination of colour sensations will readily suggest themselves.—*American Journal of Science.*

LANDSCAPE AND ARCHITECTURAL PHOTOGRAPHY.

BY S. E. STODDARD.*

I HAVE often felt that "instructions for beginners" were of a nature only to be understood after the point was reached where beginners could do without the instructions, and if it displays a lack of scientific accomplishments to make the acknowledgment, I must still say that I write my formulæ in the commonest kind of English, and aim to simplify the work to the extreme of simplicity.

The Glass is cut the required size, and allowed to remain in pickle (one quart sulphuric acid to one gallon water) for two or three days, then washed under a tap, albumenized, (solution: white of an egg to about twenty-four ounces water), and set on edge in a rack to dry. The pieces, when smoothed and bound in pairs about half way up, formed a round bundle, which, fitted with a light top of the ordinary viewing pattern, is nearly as firm as the clumsier article, and, when folded, but little heavier than a large cane.

For Travelling by rail, I have two small trunks, padded for chemicals, glass, &c. The dark-box we can carry in one hand, or, if necessary to put in the baggage car, I find that a silver half or quarter dollar laid on top of the box is a much better protection than rubber corners.

For going about the country, I have a roomy carriage, for one horse, with top (the carriage, not the horse), and rubber blanket, fitted over the dasher, coming in front nearly up to a level with the eyes. One, also, from the seat extends back over the ample body, where everything can be kept dry and secure even in the severest storms.

The Dark-box is secured at the back end, resting on a light iron frame or boot similar to those on the rear of stages. When driving, the box is closed and carried upright. When work is to be done, a strap is loosened; a part drops over back at a proper height to be worked handily from the ground, the top is extended, and we are ready for work. The same box can be taken from the carriage by simply loosening a nut. It has solid legs (two of them regulated by set screws, as I do not like the tripod arrangement for the dark-box—it's tempting providence too far), and straps for the shoulders, by which it can be easily carried.

Assistants.—I do not attempt to work alone; have found that the hours of suitable weather in the course of the year were too few to waste; and, of course, all work done under other than favourable conditions is a clear loss. I attend

simply to the camera, carefully selecting points, and making all exposures. The dark-box is in charge of Charles Oblenis, who has been with me several years, and to whose skill and careful manipulation is due no small share of what you have been pleased to compliment in the results obtained.

Arrived at the place to be covered, I secure the services of some boy—sometimes two—choosing one who looks as though he was wide awake, and with an extra inducement for quick time, set him to running with plate-holders between the camera and dark-box. You who have climbed hills or "scooted" across fields under a hot sun, to make a distant exposure, perhaps to find your tripod upset by a passing breeze, and returned with the plate to plunge your head into what, in your then condition of blood, seemed as hot as an oven, and about as dark to your contracted pupils, and in the end spoil the negative in consequence of your unstrung nerves, will bless and appreciate that boy; and when the work is done, and you look at that boy, covered with dust, and perspiration, and glory and silver, you cannot refuse him good pay for his day's work, and your own work will be better, too, for you have kept a clear, cool head at your work all the time. We use three or four plateholders; they often passing each other on the way to or from the camera, and where long exposures are necessary, one is often prepared and ready to be exposed immediately the other is taken away. After developing (one ounce protosulphate of iron, pint of water, and acetic acid to make it flow easily), the negative is flowed with—

Preservative, composed of two ounces glycerine, four ounces acetic acid, and ten ounces water, and placed in a negative box to await further action. This

Negative box is made of sheet copper, nine inches high, six inches one way, and deep enough the other to allow five by eight negatives to slide easily in separate grooves, made of strips or troughs of copper soldered fast, and affording space for thirty-two negatives. When through with the day's work, or sooner if necessary, the negatives are removed, washed, fixed (I use cyanide), washed again, and placed in the ordinary wooden negative box. I place a strip of wood across the bottom of the copper box to lift the negative above any of the preservative that may gather there, and guard against a possible stain. The cover shuts over the upper edge, and is lined with rubber to make it tight, fastened with a hasp and wooden pin. In this manner they may be kept several days without drying, and the necessity of carrying water is entirely done away with.

Redeveloper.—If weak, I place the negative (at any time after it is dry, and in daylight) back in the bath for a few seconds, then redevelop with ordinary iron developer, about one-half the usual strength, adding a little more acetic acid if it crawls when poured on.

After varnishing, I cut my stereo negatives, and fasten on other glass at the edges with gummed paper, placing the right-hand picture on the left side, to save the trouble of transposing the prints in mounting.

The Names.—Secure fine writing paper (the kind known as "onion skin" I have found best), have the names printed with the best of black ink, and all the type will bear without filling up (and, by the way, the type should be new and clean, at least not worn round the edges); let this get thoroughly dry, then cut out close to the letter, lay on the negative face down where it is designed to go, and, with a small brush, apply at the edge some kind of adhesive medium which will flow readily under the paper, make it transparent, and at the same time not disturb the surface of the negative or of the letter. I have found diamond varnish the best thing so far.

The negatives I keep in long grooved boxes, set up one on the other like shelves. Each negative is numbered from one up, and has its corresponding place in the box. I have a large book containing the views arranged in numerical order (extremely handy to select from and in making out printing lists), and large cupboards with pigeon-holes arranged in the same way to contain the finished pictures.

INSTANTANEOUS PHOTOGRAPHY.

A SERIES of articles have recently appeared in the *Bulletin de la Société Française*, from the pen of M. Sahler, on the above subject. M. Sahler seems to have made a profound study, both theoretically and practically, of the subject he has taken up, and we now place before our readers, by way of summary, the formulae recommended by that gentleman to secure pictures with rapid exposures.

Accelerating Liquid.—Into a bottle capable of holding one-tenth of a litre are put sixty cub. cents. of alcohol and one gramme of iodide of cadmium; then drop by drop is added sufficient ammonia until the last drop brings about the slightest turbidity. The clear liquid is poured off, eight cub. cents. of rectified alcohol are added, together with five drops of a saturated solution of nitrate of ammonia, and the liquid is then stirred, while drop by drop so much glacial acetic acid is put in to render the liquid clear again, only leaving at the bottom of the vessel a small precipitate of hydrate of cadmium.

Collodion.—Five grammes of collodion pyroxyline are weighed; this is put into a wide-mouth bottle and well corked, where it remains a month. The pyroxyline then begins to decompose and gives off acid vapours, and as soon as these are apparent by the smell, the product may be employed.

A litre bottle is taken, and into it are poured three hundred cub. cents. of alcohol; in this are dissolved nine grammes of iodide of cadmium, and then the five grammes of decomposed pyroxyline, together with another five of undecomposed cotton, are added. Stirring the while, there is added by degrees ether (of 62°) enough to dissolve the pyroxyline. Finally, the bottle is filled with a mixture of alcohol and ether.

The collodion is tested by pouring some of it upon a glass plate. If the film is not stout enough, a little pyroxyline is added; if it is ropy, more alcohol should be added. Then, in the open air (to prevent one breathing the injurious fumes), thirty drops of bromine are permitted to fall into the bottle.

The decomposition products of the pyroxyline oxidize the alcohol and change it into aldehyde; the iodine displaced by the bromine combines with the nitrogenous oxides, when a similar noise will be heard to that made by a hot iron being thrust into water. Iodate of chromium is formed, which subsequently combines with ammonia.

The accelerating liquid is shaken up, allowed to remain for five minutes, so that any coarse particles may sink to the bottom, and then three-fourths of the contents of the bottle is poured into the collodion. If the latter becomes turbid, it is filtered, and then two drops of ammonia are added.

If the collodion does not become colourless within ten days, then one or two drops of ammonia are added. It does not matter if it is a little turbid. It is put into long narrow bottles and permitted to stand until it is clear. It should be of a light yellow colour; if colourless, it is tinted before use every time with a few drops of tincture of iodine. It will keep good a very long time.

If the pyroxyline has been too much decomposed, the collodion will not adhere to the glass; a little ordinary iodized collodion is then added to it. When the collodion grows very old its sensitiveness may be materially increased by the addition of one or two drops of the under-mentioned reducing fluid. In fifty grammes of alcohol are poured six drops of aldehyde and three drops of ammonia. This solution must remain some days before it is used. Still more sensitive becomes the collodion by the addition of one or two drops of an extra accelerating fluid, composed as follows:—Into fifty grammes of alcohol are put eight drops of aldehyde and three decigrammes of caustic potash; after standing a fortnight the fluid becomes of a dark brown colour, and ready for use. The collodion is allowed to remain for some hours, and before use the upper portion is poured off.

The so-called Mann pyroxyline does not yield any acid fumes on keeping. When this is mixed, there should be added, before the iodide of cadmium is employed, eight drops of the extra-accelerating fluid to the alcohol, and no ammonia afterwards.

Dry Collodion.—The collodion above described requires no covering or preservative. Its sensitiveness is improved by a solution of fifteen centigrammes of resin for every hundred cub. centimetres of collodion. The maximum sensitiveness of this collodion is, however, reached by employing with it a solution of tannin.

The developer, and mode of treating the negative, will be given hereafter.

INCONGRUOUS COMBINATION IN PHOTOGRAPHS.

At a recent meeting of the Chicago Photographic Association a paper was read by Mr. P. B. Greene, criticizing the art qualities of a photograph illustrating an American journal. After severely condemning it as the poorest picture he ever saw, and expressing a conviction that such illustrations did more harm than good, he went on to remark:—

"Almost any subject will make a good picture if properly handled, but always choose the best when they are to be found. One of the worst errors photographers have made during the few years past is the use of too many accessories and scenery backgrounds. I have yet to see the first photograph where the drawing and lighting in the scenery background agrees with the figure or subject of the picture. The same fault is plainly to be seen in all landscape views, where the sky has been printed in with another negative. If our journals would give a good, honest criticism, pointing out the faults as well as the good qualities in the pictures they use for illustration, photographers would be benefited. A poor photograph, honestly criticised, is many times quite as instructive as good ones.

"In closing this paper, I wish to call your attention to a criticism of Ruskin, on one of Claude's paintings, and which I think can be profitably considered while studying our illustration: 'The False Idea of Landscape.—The Mill, by Claude.' The foreground is a piece of very lovely and perfect forest scenery, with a dance of peasants by a brookside; quite enough subject to form, in the hands of a master, an impressive and complete picture. On the other side of the brook, however, we have a piece of pastoral life: a man, with some swes and goats, tumbling head foremost into the water, owing to some sudden paralytic affection of all their legs. Even this group is

one too many; the shepherd has no business to drive his flock so near the dancers, and the dancers will certainly frighten the cattle. But when we look farther into the picture, our feelings receive a sudden and violent shock by the unexpected appearance, amidst things pastoral and musical, of the military: a number of Roman soldiers riding in on hobby-horses, with a leader on foot, apparently encouraging them to make an immediate and decisive charge on the musician. Beyond the soldiers is a circular temple, in exceedingly bad repair, and close beside it, built against its very walls, a neat water-mill, in full work. By the mill flows a large river, with a weir across it. The weir has not been made for the mill (for that receives its water from the hills by a trough carried over the temple); but it is particularly ugly and monotonous in its line of fall, and the water below forms a dead-looking pond, on which some people are fishing in punts. The banks of this river resemble in contour the later geological formation around London, constituted chiefly of broken pots and oyster shells. At an inconvenient distance from the water side stands a city, composed of twenty-five round towers and a pyramid. Beyond the city is a handsome bridge, part of the campagne with fragments of aqueducts; beyond the campagne, the chain of the Alps; on the left, the cascades of Tivoli.

"This is, I believe, a fair example of what is commonly called an 'ideal' landscape—i.e., a group of the artist's studies from nature, individually spoiled, selected with such opposition of character as may insure their neutralizing each other's effect, and united with sufficient unnaturalness and violence of association to insure their producing a general sensation of the impossible. Let us analyze the separate subject a little in this ideal work of Claude's.

"First, we will reduce the multitudinous precipices of the Appennines to four sugar-loaves. Secondly, we will remove the Alban Mount, and put a large dust heap in its stead. Next, we will knock down the greater part of the aqueducts, and leave only an arch or two, that their infinity of length may no longer be painful from its monotony. For the purple mist and declining sun we will substitute a bright blue sky, with round white clouds. Finally, we will get rid of the unpleasant ruin in the foreground; we will plant some handsome trees therein; we will send for some fiddlers, and get up a dance and a picnic party.

"It will be found throughout the picture that the same species of improvement is made on the material which Claude had ready to his hand. The descending slopes of the city of Rome, toward the pyramid of Caius Cestius, supply not only lines of the most exquisite variety and beauty, but matter for contemplation and reflection in every fragment of their buildings. This passage has been idealized by Claude into a set of similar round towers, respecting which no idea can be formed but that they are uninhabitable, and to which no interest can be attached beyond the difficulty of conjecturing what they could have been built for.

"The ruins of the temple are unimpressive by the juxtaposition of the water-mill, inexplicable by the introduction of Roman soldiers. The glide of the muddy stream of the melancholy Tiber and Anio through the campagne is impressive in itself, but altogether ceases to be so when we disturb their stillness of motion by a weir, adorn their neglected flow with a handsome bridge, and cover their solitary surface with punts, nets and fishermen."

PRIZES OFFERED BY THE VIENNA PHOTOGRAPHIC SOCIETY.

THE Vienna Photographic Society offers the following prizes for the solution of various problems connected with photography:—

a.—Voigtlander Medals.

1. A gold medal worth 140 ducats for a method of increasing the sensitiveness of wet plates.
2. A gold medal worth 140 ducats for a certain and rapid dry process of superior excellence.
3. A gold medal of 40 ducats for a thorough research into the asphaltes.
4. A silver medal for a collection of natural history studies.
5. A silver medal for a collection of instantaneous pictures.
6. A silver medal for a collection of lantern transparencies, for illustrating science, art, or technical matters.
7. Medals in gold (of a value from 40 to 100 ducats), silver, and bronze, for scientific research, inventions, or improvements, which are communicated to the Society or to its organ.

b.—Society's Medals.

1. Gold medal of 140 ducats for the production of type blocks having half-tones.
2. A gold medal of 140 ducats for a critical study of the reactions of chrome acids and their salts upon albumenates, albumenoids, carbon hydrates, and resins, with particular reference to the different heliographic processes.
3. A silver medal for *genre* pictures.
4. A silver medal for carbon prints produced in Austro-Hungary.
5. A silver medal for a collection of monuments.
6. A silver medal for a collection of ethnological studies.
7. A silver medal for a collection of anthropological studies.

Competitors must qualify by becoming members of the Society. Further particulars may be obtained by addressing the President, Dr. Hornig, Vienna III, Hauptstrasse 9.

THE CARBON PROCESS OF TO-DAY.

BY W. E. BATHO.*

AFTER the paper which forms the support of the image is washed off, the gradual appearance of the hitherto obscured image possesses all the charm peculiar to the development of a wet plate. In the case of under-exposure, little or nothing can be done; it is better to start again. Should the print prove over-exposed, the use of water at a higher temperature will reduce the print; but a better and safer way will be to keep the water at one steady temperature, and add a few drops of ammonia. This, in my experience, reduces the print in a more uniform manner than hot water or long soaking—that is, the more delicate shades do not go so soon as with other treatment. Yet the method for reducing a carbon print with such uniformity as to give a result similar to that resulting from correct exposure has yet to be published. The developed picture is washed with cold water, the fixing with a solution of alum follows this, again washed, then dried spontaneously.

Any spotting required is done when all is ready for the transfer. In this operation a little thought will supply the information necessary to overcome all difficulties. The pictures being formed of various thicknesses of gelatine, shown by the dark parts being in relief, there is a danger of the transfer paper not being pressed into all the hollows, to bridge over, as it were, from point to point, and so cause a defective print, shown by white lines running close to the outlines of a dark or elevated portion. The transfer paper should be made quite slimy, so as to enable the operator to mould it to the picture, and ensure absolute contact. Sometimes a transfer paper either has not sufficient gelatine thereon, or has become exceedingly hard by long keeping, so that it cannot be got into the required state. In this case dipping the paper into a solution of gelatine at the time of using proves a

* Continued from page 258.

remedy; sufficient adheres to the paper to fill up the hollows of the print, and so brings the print and paper into contact.

It seems to me that in the manufacture of a transfer paper attention should be given to the selection of a right material upon which to spread the gelatine, for the grain of the transfer paper sometimes shows unpleasantly in the whites. Should even a higher price have to be paid, the use of a fine paper is advisable. Another way of arriving at the same end is to load the gelatine with a white pigment to hide the grain of the paper. I have chosen sulphate of barium, which was produced in the warm solution of gelatine already containing a soluble baryta salt, by the addition of a soluble sulphate; this method enabled me to use what would otherwise have been a paper altogether too rough for fine work.

The transfer paper having been applied, it is allowed to become surface dry, when it is well starched. The mount, previously damped between blotting boards, is also starched and pressed into contact with the paper. This is then placed under pressure for some time, and allowed to dry, when the print will come off; it can then be trimmed as the fancy dictates.

I have said the mounted print is left under pressure for some time—this may mean a few minutes or a few days. It appears, however, that a print dried rapidly has not so fine a surface as one dried slowly, and the length of time the print is under pressure prolongs the time of drying, owing to the necessarily slow evaporation.

That there are difficulties in the way of pigment printing the most violent carphophile will admit. To calmly meet them is the surest way to success; to ignore their existence is not an evidence of sanity. That it has difficulties ought not to be a source of regret, for when the public are educated to prefer the permanent to the fleeting, the very difficulty of meeting the want will tend to weed out, by a process of selection, those not suited to the times. Be this as it may, I do not envy the man who has so little sound interest in the advancement of our art science as not to wish every success to the carbon process.

CARBON TRANSPARENCIES FOR ENLARGEMENTS.*

The diapositive to be employed for enlarging purposes must be differently constituted to pictures intended for window ornaments, lamp shades, and the like. Instead of a vigorous and plastic diapositive of agreeable tone, which is quite opaque in the deepest shadows, it is necessary to produce a thin and delicate image, which will allow the light to pass through everywhere. Such an image is not to be obtained with black tissue employed for ordinary stereoscopic pictures and stereoscopic slides, and which contains a great deal of pigment, but requires a tissue with a finely ground pigment, in which there is a good deal of carmine and Venetian red, and very little bone black.

Its preparation in the bichromate bath is the same as that of ordinary tissue. As it comes out of the bath it is put face downwards upon a well-cleaned glass plate, covered with a piece of waterproof material, and scraped with the squeegee. It is permitted to remain upon the glass plate for five minutes, and is then drawn off and hung up to dry. Its exposure under the negative takes about half as long again as is the case with a paper positive.

The imprinted tissue is moistened in the ordinary way, and placed upon a well-cleaned and faultless plate of glass, the squeegee being pressed upon the impression to ensure its adhesion. In this case the plate is not rubbed with wax; on the other hand, it may be previously coated with very thin structureless normal collodion, and laid in water until the fatty marks disappear, when the tissue is adjusted in the usual way.

The best results are secured, however, it seems, by the use of a glass plate which is coated with gelatine instead of collodion. The so-called reticulation, or network markings of the tissue which sometimes appear (and which are due to the temperature at which the tissue has been dried, although the phenomenon also seems inherent to certain classes of gelatine) are then never to be met with. As the quality of the enlargement depends upon the nature of the diapositive, every defect in the latter becoming enlarged, it is well to employ a gelatine coating whenever this reticulation is apparent even in the slightest degree. The plate is in this case carefully cleaned and dusted, and then the gelatine solution is prepared as described by Mr. Willis, in Wharton Simpson's YEAR-BOOK, 1876. Twenty-six grammes of Nelson's gelatine are put into eight hundred grammes of cold water, and after the lapse of an hour the vessel is placed in hot water; the gelatine then dissolves. Next, in one hundred and sixty grammes of hot water is dissolved one gramme of chrome alum, which is gradually added to the gelatine solution, the latter being stirred the while. The solution is filtered through fine muslin, and while yet warm the glass plate is coated with it, the gelatine being poured on like collodion, and spread with the aid of a glass rod. The drying takes place in a locality free from dust. The preparation of the plates with gelatine may be undertaken some time previously, the same being kept in a box with their backs properly marked. Before development the dry gelatine plate is dipped into cold water, and after a minute the exposed tissue is pressed against it. After passing over the squeegee, the tissue is weighted, allowed to remain five or ten minutes, and is then developed.

When impressions of the greatest sharpness and delicacy are required, Monckhoven's plan should be adopted. The main thing is to impart to the tissue a mirror-like surface. A carefully cleaned piece of patent plate, somewhat bigger than the bit of tissue to be sensitized, is coated with very clear normal collodion, and dried for some hours in a dust-sheltered spot. The plate is neither waxed nor put into water.

The tissue is put into the bichromate bath, and then its gelatine surface placed upon the plate, squeegeeing as usual. The tissue is permitted to dry upon the plate. It will remain perfectly good for a week in this way, adhering to the glass. If several such plates are at hand they are placed one over another, so that the air cannot act upon the back of the tissue. Bubbles must be avoided as much as possible, for as soon as the tissue is laid it cannot be lifted without detriment to the collodion film. In an average temperature the tissue dries in three or four hours. As much of the tissue is cut off as is necessary, and this is then found to have a mirror-like surface, which lies in close contact with the negative in printing. The printing is done in the ordinary manner, and before development the tissue is put into water soured with hydrochloric acid (about one to one thousand). The tissue must remain in here longer than usual, so that the gelatine is thoroughly impregnated with water, otherwise reticulation will set in. The tissue is placed upon a faultless glass plate, without collodion or wax, and squeegeed in the usual manner, air-bubbles being especially avoided. If the tissue does not adhere well to the plate, a weight is put upon it; in half an hour the tissue will lie perfectly flat. Before this, the development must not take place.

It is begun with luke-warm water (23° C.), and afterwards warm water is made use of. If the collodion separates on development, then it is necessary to wait some hours before proceeding with the operation; or the plate must be previously coated with collodion, gelatine, or a thin solution of gutta-percha in chloroform. This coating must be quite dry; the tissue will adhere to it then very firmly.

The diapositive sometimes requires to be intensified; in the case of gelatine plates, however, no intensifier can be

used, as the substratum then gets discoloured. In other cases, or when collodion has been used, the intensifier may be employed with advantage. Two solutions are necessary:—

a.—	Permanganate of potash	...	10	grammes
	Water	...	500	"
b.—	Sugar...	...	5	"
	Ammonia	...	2	"
	Water	...	500	"

Equal parts of a and b are mixed in a dish, and the dispositive put in. Its colour changes to a yellow; and the process must not be carried too far. When dry and laid upon white paper, the result should appear somewhat darker than a good paper print.

IODISING COLLODION WITH ANILINE SALTS.

BY DR. EDER AND CAPTAIN TOTHE.*

THE idea of employing organic iodides and bromides for mixing with collodion is already an old one. The best suggestion made in this direction was that of Van Monckhoven, who recommended the use of iodide and bromide of ethylamine; and the observation which was made to the effect that iodide of ammonium with alcohol forms, after a long time, iodide of ethylamine, and that before a collodion prepared with the latter would have the properties of a ripened product, supported this recommendation of Monckhoven. The production of iodide of ethylamine is, however, a very difficult matter, and, practically, the employment of the compound for iodising collodion is inadmissible.

But the interesting result showing that the alcoholamines of the fatty acid series yield iodising salts has induced us to undertake a series of experiments with the amines of the benzole series. We chose aniline, the prototype of the series, as the starting point of our research; it possesses, but in a much less degree than its salts, the property of absorbing iodine and bromine.

Hydro-iodate and bromo-iodate of aniline were produced by taking nitrate of aniline three parts, and dissolving it with as little water as possible, with iodide of potassium three parts, or bromide of potassium two parts, the solution being afterwards treated with alcohol; the filtrate from the crystalline precipitate (saltpetre) yields, after vaporising on the water bath, slightly coloured, needle-shaped crystals of aniline salts. With this we prepared two descriptions of collodion:—

1. One simply iodised by mixing a solution of 4.0 grammes of hydro-iodate of aniline in 50 grammes of alcohol with a threefold volume of a two per cent. normal collodion.

2. One bromo-iodised by means of a solution of 8.4 grammes of hydro-iodate and 0.5 gramme of hydro-bromate of aniline in 50 grammes alcohol.

The collodions became coloured immediately after mixing, and assumed a strong golden yellow colour; they had the same iodide and bromide contents as an ordinary negative collodion.

Both, we found, gave equally unsatisfactory results. Sensitized in a ten per cent. silver bath, they both gave uniform films, but thin, flat pictures. The time of exposure must be longer than in the case of ordinary collodion, although not very much so.

As might be expected from the proneness to decomposition of aniline compounds, the aniline collodions were both of them rapidly decomposed, and in the course of two or three weeks had assumed a deep red colour.

We take the liberty of communicating these unsuccessful results of our investigation, as they serve to complete our systematic knowledge of the iodising of collodions.

* Read before the Vienna Photographic Society.

COLLODIO-ALBUMEN AND OTHER DRY PROCESSES.

BY GEORGE W. HEWITT.*

DURING the last few years I have tried almost every dry process that has appeared from time to time in the journals, as the multitude of bottles, compared with the paucity of good negatives, in my possession will attest. I have been in search of the "philosopher's stone" of dry-plate photography—a process that would do everything better than "wet," and be no trouble in the bargain. My course, apparently straight ahead to this result, has really been in a circle, and has brought me to the point from which I started some five years back. In the time above mentioned I have had recourse for my preservatives to the henroast, the kitchen, the brewery, and the apothecary. I began with albumen, from that to tea and coffee, thence to beer and porter, and finally squills and nux vomica. I gave these all a trial, as well as raspberries and serum of milk. During this siege with bath process I also had on hand series of experiments with emulsions, both washed and unwashed, generally with an excess of something in them always ripening, but seldom ripe. They gave me no end of trouble, and, when failures occurred, it was a great satisfaction to be able to lay the blame on the cotton, the unsuitability of which is one of the strong points of the emulsion process, and will cover a great amount of chemical blundering. Gelatin, the most seductive of all, did well for a time, but eventually brought me into red fog and blisters. The moist process I did not attempt, but for the purpose I conceived a modification of the hot-water process, as follows:—Add a little of the decoction of mustard-seed (lately advocated) to the hot water in which the plate is immersed, dry off, and give it a dose of syrup of squilla, laudanum, and nux vomica, which will produce a profuse perspiration, and keep the plate moist for a considerable interval. I have not tried this, but have seen the day when I would have done so. After all my experience in trying published formulae in this and other branches of photography, often as conflicting as they are numerous, has led me to the conclusion that it would be better and appropriate if the heading to some of our photographic periodicals of the day was the opening address of King Powhatan to his congress of Indians, viz.: "All those laws we made yesterday, we hereby now repeal."

The following I offer simply as the result of all this experimenting, as far as my own experience is concerned. The most desirable quality in a dry plate is the certainty and uniformity of result, irrespective of its rapidity. It should admit of considerable latitude in exposure, have good keeping qualities both before and after exposure. An adhering film that would pass through all the necessary manipulation without slipping or blistering, should be free from defects in the film, from blurring and solarization, and should not require backing. The quality of the finished negative is the standard that should guide in the selection of a process, and not the rapidity of the plate, or the simplicity of its preparation. The object of photography is to produce a representation on suitable material of a subject selected. Chemical manipulation is essential to the attainment of this end, but we must bear in mind that it is this representation in pictorial form that we require, and not an ingenious or simple solution of a problem in chemistry. Photography opens up a vast field for experimental chemistry, and it is a very interesting one, and also very necessary for the advancement of the art; at the same time, if the means are at hand to accomplish what we require as artists, we may leave the experimental part of it to those who have the time and the inclination to follow it. A process having the qualities above described has been before the photographic community for the last twenty years, but has been lost sight of by many in the present conditions of chemical complications. It is a slow process; in fact, with me all dry plates

* Read before the Photographic Society of Philadelphia.

are slow. The most rapid plates I have ever made are the gum-gallic plates, with a highly bromized collodion and strong nitrate bath. On a well-lighted and open view these plates, when freshly made, will work quite as rapidly as wet plates; but this comparison ceases when the plates are a few weeks old, and the subject has heavy masses of foliage in shadow, or, in fact, the usual landscape effects. I have invariably found in this case that it required at least ten minutes wet exposure to bring up all the detail. I have noticed this quality in dry plates, that, while responding quickly to the well-lighted parts of a subject, the film is not impressed in a corresponding degree by the weaker vibrations of light; and, consequently, in exposing for the shadows, the high lights always receive more time than they really require, and it is on this point the generality of dry plates break down, the lights becoming thin and solarized, losing their detail.

With the very rapid emulsion plates I have had little experience, but that has taught me that chances of failure increase in direct ratio with the sensitiveness of the plates, as well as blurring, defects in the film, and difficulty in timing and development. I know that rapid emulsion plates can be made to work as quickly as wet, and do it well. There is no doubt on this point. But I am speaking now from my own experience, and I have never met with any emulsion process that equalled in its results the original one of M. Carey Lea, as published by him in 1870. I do not think any improvement has been made of this process, even by himself. As to the reliability of rapid emulsion plates, some years ago, while photographing on the Wisconsin, using gum-gallic plates, and giving from three to six minutes, I met a gentleman taking an outing for the same purpose. He informed me he was working emulsion, and giving from four to six seconds' exposure. I afterwards saw the negatives he made on that occasion, and they were excellent and fully timed. Some time after I met him again with his camera, but this time his object was to make negatives of an open-air group of the members of a society out of town. I remarked, that with those rapid plates of his he would have no difficulty; but he astonished me by replying that, as it would be the only chance he would get at the party, and as they were very anxious to have the pictures made, he had left his rapid plates at home, but instead had a few slow plates that he felt sure of. I judged, from what he said, that when he went out for the fun of the thing, he took the rapid plates; his slower ones when he meant business. This gentleman is one of the most successful workers in emulsion in the city, and his experience seemed to coincide with my own, that, for reliability and perfection of result, a slow process will necessarily be the choice.

The negatives that I have brought for your inspection this evening were produced by a process of this character, the details of which I will now describe. The only novelty that I claim for it is that there is nothing new in it.

The plates are albumenized with Ackland's albumen 1 part, water 25 parts, which I keep in this proportion in a comparatively large quantity, and filter off as much as I may require. If anything, it improves with age. The nitrate bath, 40 to 45 grains to the ounce, with 5 drops of glacial acetic acid to each ounce. The collodion: any good commercial sample will answer, but my best results have been made with the following, an English formula, the best collodion for any purpose I have ever tried:—

Anthony's snowy cotton...	...	6 grains
Ether, concentrated	...	4 drachms
Alcohol (78°)	...	2½ "
Add to this 1½ drachms of the following:—		
Alcohol	...	6 ounces
Iodide of cadmium	...	112 grains
Bromide of cadmium	...	40 "
Chloride of cadmium	...	16 "
Iodide of ammonium	...	80 "
Bromide of ammonium	...	20 "
Iodine	...	4 "

The preservative: Ackland's albumen 1 part, distilled water 4 parts. A solution of gallic acid in alcohol, in the proportion of 60 grains to the ounce, filtered. These are all the chemicals required, and they can all be kept in stock.

(To be continued.)

Correspondence.

CHEMICAL INSTRUCTION FOR PHOTOGRAPHERS.

DEAR SIR,—Reading a short time back an article in the *News* entitled "Ought Photographers to Understand Chemistry?" and your appropriate observations, brought to my mind the idea of examinations and certificates for aspirants intending to follow the photographic profession.

Some years ago I was the first to bring this subject before the notice of your readers, and think with the aid of the Photographic Society it could be well carried out. If we look around we find that such examinations and certificates are required by Government and by nearly all professions. Why, may I ask, should our beautiful art be degraded by the want of systematic education of its professors?

As an example of the benefit of such a course, I may point to a class of shop-keepers entitled chemists and druggists. In my younger days very few indeed had the slightest claim to the title of chemist, and the whole body were little more than what might be considered medical grocers, better termed druggists. The institution of the Pharmaceutical Society, and the late Act of Parliament concerning the sale of poisons, has entirely taken the profession out of the hands of ignorant pretenders, and it now stands second only to that of the medical man himself. Though they seldom have time for research, some few persevere, and become analytical chemists. Of these bright stars I am not speaking. With pharmacy and therapeutics, photographers have nothing to do; yet their chemical knowledge should be of a far more practical character than is required by the before-mentioned class, and it should be directed towards those objects which their art renders necessary. There are so many scientific operations nearly every day becoming necessary through the advancement of photography, that it is difficult to say where the student's knowledge of chemistry should cease, or in what direction his researches would be best directed. But if I might venture to recommend, I should say let him acquire a sound knowledge of the general outlines of the science, and then direct his attention more particularly to metallurgy, the metallic and other salts, chemical re-action and decomposition, and the gases.

With your leave, in a future paper, I will try and sketch a systematic and general outline of what a photographic student's education should consist; not with any intention of being dogmatic, but with the hope that the matter may be taken up and commented on by wiser heads than mine. There is no knowing, when a seed is planted, what a flourishing, fruitful tree it may become.—I am, dear sir, yours truly,

JAMES MARTIN.

5, Clarence Place, Alfreton, May 29th.

IMAGE ON THE EYE OF A DEAD BODY.

SIR,—Dr. Vogel's wonderful account of the photographic properties of the retina of the eye is most interesting, not from a photographic point of view only, but also in many other regards.

One great benefit which suggests itself as a practical corollary of this discovery, when it shall have been further developed, is its possible application to the identification and detection of murderers. In many instances, no doubt, the image of the assassin must be the last one that appeals to the fading vision of the victim. In such cases it might

prove of great service to the police if the eyes of the corpse were withdrawn from the head, and treated in such a manner as to secure the image last imprinted on the retina. Glass counterfeits might be substituted in their stead, if desirable, for the identification of the body.

It is not, of course, implied that entire reliance should be placed upon any such means, for it is, indeed, evident that suspicion might often be cast upon innocent persons; but merely to hint a possible addition to the means of discovering and bringing to justice the perpetrators of crime.—I am, sir, your obedient servant, H. WILSON.

[The notion that an image of the murderer might be found imprinted on the retina of his victim has often been discussed, and generally dismissed as improbable by scientific men, as until the recent discovery to which you refer there was no evidence that vision was a photographic process. Even in view of the late experiments, it is very doubtful, we think, whether any practical application can be made of the facts in the way of identification.—ED.]

A SIMPLE AND EFFICIENT DROPPING BOTTLE.

SIR,—I beg to enclose the sketch of a very simple dropping bottle, which will, I do not doubt, find favour with those engaged in dry plate work necessitating alkaline development. The dropping bottles in ordinary use have several faults: the cap of india-rubber, if not used for a short time, gets hard, and leaks; the stoppers have to be removed while travelling, and they are by no means cheap. The simple one shown in the drawing,

which was suggested to me by a friend, answers admirably in every respect. As will be seen, it is composed of a baby's teat, a square bottle (most convenient for packing), a piece of glass tube, and a cork. In travelling, the solutions may be kept in their place, there being no necessity for removing the cork, as the liquid will not run into the teat. Large letters cut out of paper, A B V S, can be pasted on the broad side of the bottle, or could easily be etched in by fluoric acid. The teats being composed of a superior sort of rubber, will last a considerable time, and could, in case of accident, be easily renewed for a trifling sum.

WALTER W. B. WOODBURY.

[A somewhat similar dropping bottle was recently described by one of our correspondents. All who have tried ordinary india-rubber will at once appreciate the advantage of using the teats mentioned by Mr. Woodbury.—ED.]

Proceedings of Societies.

WEST RIDING OF YORKSHIRE PHOTOGRAPHIC SOCIETY.
The ordinary meeting of the above Society was held at the Odd Fellows' Hall, Bradford, on Monday evening, the 7th inst., the President in the chair.

The minutes of previous meeting having been confirmed, two new members were elected.

The SECRETARY then read a communication from the Glasgow Society, regarding the Autotype patents, when it was decided, on the motion of Mr. Crosthwaite, to adjourn the matter until the October meeting.

Mr. JOHN SMITH then read a paper entitled "Stray Thoughts on Carbon Printing," and exhibited several pieces of apparatus designed to promote pigment printing; viz., a mechanical sensitizing dish, with a pair of rollers carrying an endless band on which the tissue was fastened (the rollers turned the tissue thus immersed); an ingenious clip for drying tissue; a drying box; and a frame for preventing the mounted picture from springing from the glass in drying, at the same time leaving the back of the card exposed, to facilitate the evaporation of the moisture.

Mr. GREAVES exhibited, in conjunction with Mr. SMITH, one of his new patent printing and tinting frames for chromotype work; also a case of small vignettes in carbon, produced by his new method, which were considered by those present as almost perfection. The negatives were fine specimens of delicate manipulation, while the gradation of tint in the vignetting could not be surpassed. The various pieces of apparatus were inspected with great interest by the members, most of whom are much interested in permanent printing, Messrs. Smith and Greaves being frequently called upon to answer some question regarding the apparatus.

Mr. SACHS considered the machine for tissue sensitizing unsatisfactory. He certainly thought the use of gloves would prevent the deleterious action of the bichromate on the system, and this appeared to be the only advantage claimed for the machine. There was, he thought, a great probability of the tissue in its immersion carrying with it numerous air-bubbles, which would require removing. Taking all things into consideration, he was of opinion that hand-sensitizing was preferable. The drying-box he thought practicable, and the printing frames of Mr. Greaves simply invaluable. He had tried several frames for the purpose, but had seen none to come near Mr. Greaves' for economy of time and excellence of construction. In his own establishment he used Lambert's, and thought they were superior to Higginson's, but Mr. Greaves' was far better than Lambert's. A great advantage was gained by manipulating nine at once. As to the vignettes, he could not praise them too much, as he had personally inspected the method, which was so simple that any boy could print them. As to the method of producing combination negatives in the camera, the great drawbacks were that the least inequality in the negative would prevent an even tint being printed round the margin, and the most scrupulous cleanliness was necessary, as a slight defect, which would never be noticed in a plain picture, would prove fatal to the marginal tint.

Mr. SMITH replied that he did not advocate the use of any such method commercially, but it was a ready mode for amateurs not desiring to go to the expense of registering frames.

Mr. CROSTHWAITE remarked that Mr. Smith's paper taught some very useful lessons; though not an exhaustive epitome of methods and formulae, it showed plainly that equally good work might be produced by persons working very diversely, both in methods of manipulation and formulae. It served to demonstrate, most unequivocally, that if an experimenter failed to produce satisfactory work, it was very probable that the principal fault lay with himself, and not the material. It had been very much the fashion of late to decry the material supplied, and desire a change; but there was such a thing as falling out of the frying pan into the fire. A good article, uniform in manufacture, was what was wanted, and he was afraid it would not be obtained by splitting up the manufacture, and having a number of tissues of varying qualities and colour in the market, which would vary as much, or more, than albumenized paper, that fruitful source of complaint. Carbon printing seemed to be very much like dry-plate work; with the same batch of plates one operator would produce clean, brilliant negatives, whilst with the same material another would get grey, foggy, worthless results; this, in most cases, arose simply from a want of experience in that particular method. Just the same reasons applied to carbon printing. When an operator had become perfected in a certain process by years of experience, it was not to be expected that he would at once jump into successful practice in a totally different method. There must be a certain amount of practice and familiarity with the conditions under which he was working, otherwise success would be only occasional, and even then, more by good luck than good management. It was important, too, that the apparatus and arrangements be of the best, and most easy of manipulation;

and some of the apparatus shown that evening was of that kind, and seemed likely to be of very great service in the cause of permanent printing.

Speaking of Mr. Greaves' vignettes, Mr. JENKINS remarked that he had seen them produced, and could speak for the ease with which they were vignettised, as the specimens shown were not specially got up, but simply selected from the daily work.

Mr. SACHS said that carbon vignettes had been produced for a long time; but the tinting difficulty had never been so easily overcome until now that Mr. Greaves had perfected his method.

Mr. COOKE exhibited a tent for out-door wet-plate work, of a very compact and complete character, which was inspected with much interest by the out-door workers.

The usual votes of thanks were then awarded to Mr. Smith for his paper, Mr. Greaves for his apparatus shown, and to Mr. Cooke for the exhibition of his portable tent.

The Society then adjourned their next in-door meeting until October; but arranged for an out-door meeting and excursion on the 6th of June, to Kippenden.

The proceedings then terminated.

Talk in the Studio.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—At the next meeting of this Society, on Thursday next, June 7th, in the Rooms of the Society of Arts, John Street, Adelphi, a paper on the "Nitrate Silver Bath" will be read by Mr. B. J. Edwards.

GLASS FOR NEGATIVES.—We have been favoured with some samples of the glass sent out by Messrs. Shrewsbury, Howard, and Co., of Digbeth, Birmingham, under the name of "imprimatur plate." The surface is singularly good and free from blemish; and as the price is less than patent plate, it can scarcely fail to be welcome to photographers. It possesses an unusual advantage in having the most perfect surface marked with the letter S at the corner, so that the operator is left in no doubt as to which side should be coated with collodion. Their plates for microscopic objects are capital.

THE PHOTO-ARTISTS' COMPANY.—This Company, under the directorship of Mons. Piquépé, has just issued a new catalogue, which will interest photographers. It is illustrated by a capital example of retouching, and side by side with it a print from the untouched negative, which well illustrates the skill with which the retouching is effected.

PAYMENT AT THE TIME OF SITTING.—Our advertising columns contained an announcement of an inscription for the studio or specimen room, with an intimation, which must attract the attention of all, that all photographs must be paid for at the time of sitting. A specimen of the announcement forwarded to us is neat, bold, and ornamental.

To Correspondents.

G. and R. LAVIS.—The three cabinet portraits have been received and handed to our Publisher, who undertakes attention to registration for our readers. There were no stamps in your letter or parcel. The stamps, together with full particulars, as name of portrait, owner of copyright, &c., must be sent to our Publisher. Any kind of copy, whether enlarged or reduced, would constitute an infringement of copyright.

J. K.—The data you give in regard to the portrait studio required is somewhat too vague to permit of very definite advice. One of the simplest and most useful consists of an oblong glass room with span roof: about twenty-six feet long by twelve feet wide, fourteen feet at the ridge, and seven or eight feet at the eaves: both ends opaque: the side and roof, facing north, to be of glass, except about five feet at each end, the glass at the side coming to within about twenty inches of the floor: the south side and roof about half as much glass as the north side.

B. G. F.—Unsize paper should be used in making papyroxyline. Swedish filtering paper answers well; ordinary blotting-paper may be used. In our experience, pyroxyline made from paper has given a little more intensity in the negatives than that made from cotton.

T. J. P.—The most probable cause for the dirty yellow stains at the margins of the prints, which you describe, is the presence of hypo in the mounts, many samples of pasteboard having such traces, used in the manufacture. There is no remedy. Sufficient quantity of a fresh thirty-grain solution is all that need be added to your bath.

OSBORN.—There is no work, that we know of, devoted to the subject of producing photographic lantern slides. There have been many articles on the subject in the back volumes of the PHOTOGRAPHIC NEWS, and also in the YEAR-BOOK OF PHOTOGRAPHY.

T. W. MARTEN.—Our Publisher will send what you require. Regarding the carbon process, if you take any one of the series of lessons which have appeared in our pages, and follow instructions carefully, we think you will succeed. The Manual issued by the Autotype Company contains, also, very complete instructions. It you will state your difficulties at any time, we shall have pleasure in giving you, in this column, special hints thereupon. We do not know of any better mode than these of obtaining written instructions. For a dry process, we do not know of any better, or more likely to suit your purpose, than the coffee process, described in last year's volume, and also in our last YEAR-BOOK. We shall have pleasure in seeing at any time examples of your work.

R. M. H.—It does not necessarily follow that because carbon printing is progressing, and entering largely into general use, that silver printing is falling off in precisely the same ratio, as you argue. Carbon is employed to a large extent in work, such as art reproduction, which would not, without a permanent printing process, have been done at all. It is possible that silver printing may eventually pass entirely out of use; but not for very many years, and quite possibly never. It is probable that in many matters permanence may be unimportant; a temporary duration may be all that is required. You are in error in supposing that the earlier photographic processes have passed out of attention and ceased to be practised because they were not permanent. A properly produced and properly preserved Daguerreotype was quite permanent, and many are now in existence as good as they were when first produced. A print produced by the calotype process is generally found to be more permanent than an albumenized print. If a print is properly fixed and washed, the process of enamelling tends to secure its permanency.

D. L.—A collodion positive on glass, backed with maroon velvet, is generally brighter and less heavy looking than a ferrotype. The direct contact of the image with the dark surface of the latter produces a heavier effect than the velvet backing of the image on a plate of glass. The non-inverted coloured glass positives to which you refer were collodion positives, treated with a whitening solution which contained salts of mercury. The powder colours were applied, with as much force as possible, to this whitened surface, and this was then treated with a thick spirit varnish, specially prepared for the work. The application of this varnish carried in the colour into the porous film, so that it was seen vividly from the reverse side of the picture, which viewed from that side was, of course non-inverted. Much pains and skill were required to produce successful results; but when well done, the pictures were very fine, and had all the appearance of very delicate miniatures in oil. We do not know of any one who produces such pictures at present. The materials were sold by Newman, of Soho Square.

E. H. DERRAM (Boston).—The sample of tissue received. We will try it, and report.

J. H. CORSCADEN.—Many thanks. In our next.

Several Correspondents in our next.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

THE MEDAL FEVER, AND FORTHCOMING EXHIBITIONS—PHOTOGRAPHERS' ASSISTANTS AND THEIR DUTIES.

The Medal Fever, and Forthcoming Exhibitions.—Photographers cannot complain just now of want of encouragement. Throughout Europe a prolific shower of medals may shortly be expected, and it will be hard indeed if any one who strives for favours should not be successful in catching some of the drops that are to besprinkle the photographic pastures. Amsterdam promises medals, Vienna promises medals, Paris promises medals, and even the Photographic Society of London announces a distribution of similar favours. It will be quite worth while "doing a picture," for a lucky candidate may even hope to carry off three or four awards with the same productions. All the societies seem to be striving to out-bid one another in the hope of securing competitors in the race, for whether it is pictures or processes that are wanted, the same inducements are held out. We do not propose to enter into any discussion as to the advantages or disadvantages involved in the award of medals, and only hope that the anticipations made by the several bodies will be fully realised. One thing, however, connected with the promising of medals for the fulfilment of certain problems always has a disappointing effect upon our mind: the result is invariably so disproportionate to the loud trumpeting and fuss with which the conditions are made known. It may be for a dry process that the prize is offered. What is wanted, we have been informed over and over again, is a dry collodion process which shall be as good as wet, as certain in its action, and as simple in its nature; it is to yield prints beyond reproach, and, if possible, be upon a basis as transparent and convenient as glass, and yet tough and flexible; in a word, perfection is asked for. The result, as we have said, is not perfection. In fact, the successful competitor usually brings forward a process which has neither novelty nor excellence to recommend it, and the prize is awarded not because the problem has been fulfilled, but because one hardly knows what else to do with the medal. So far as regards photographic exhibitions, we think that the main thing to be arrived at is to produce a collection of photographs which, like a collection of paintings, is worth looking at from an art point of view only. By all means let us have encouragement of the technical and scientific aspects of photography; but if the public are invited to view an exhibition of photographs, and the latter is to be made interesting and worthy of a visit, then the only aim to be kept in view is to make the collection one of pictures essentially. Again, the pictures, to our mind, should be such as can be examined without too close an inspection. Tiny prints and bijou productions are very well in their way, and should doubtless have a well-lit corner allotted to them; but if we are to make the looking at photographs a favourite pastime with those who visit galleries, we must have broader and bolder photographs altogether. It is the photographer's aim to get the public to look at his pictures, and to ensure this the public must not be inconvenienced, but rather enticed to do so. An exhibition made up of small pictures is uninteresting at first sight to photographers themselves; how much more insignificant does it appear to the public! A spectator on entering such an exhibition is disappointed, and, although on close examination he finds many beauties to admire, he never altogether gets over the first impression. It is surprising what an influence Mr. Crawshaw's prizes had upon the London exhibitors; last year's show, although it contained a good many of what may be termed loud enlargements, consisted for the most part of small work, and hence contrasted unfavourably—at any rate, on the first coup d'œil—with exhibitions that have preceded it. We

hope that those who propose "going in to win" some of the medals that are to be sown broadcast will attempt work on a larger scale than that hitherto exhibited. Photographers have, indeed, much to thank Mr. Crawshaw for already, in inducing them to leave the narrow limits within which they used to work. Carte and cabinet work was what most confined their attention to, and larger pictures were a rarity indeed. This is no longer the case, happily, and we sincerely trust photographers will go on improving their work without relapsing into their former prescribed limits. There is no lack of encouragement now, and those who believe that success and progress are attained by a lavish distribution of medals may congratulate themselves to their heart's content.

Photographers' Assistants and their Duties.—With the prospects of introducing carbon and Lichtdruck printing in the studio, there should be some change for the better in the position of photographers' assistants. It will be necessary for them to be better trained and have a wider knowledge than hitherto; but possessing these qualifications an operator could not fail to secure good wages. An assistant at the present moment, who can print well in carbon—that is, produce impressions in permanent pigments equal to those usually obtained upon albumenized paper—who is conversant with the operations of wet and dry plate photography, and can take a clean and successful negative by either method, and who is finally an adept at lithographic printing, would, we should think, be eagerly sought for. And yet there is no reason whatever why such assistants should not be forthcoming, for there must be many establishments now-a-days where all this is to be learnt. Indeed, a few years hence, it is very possible that permanent prints in carbon or in fatty ink will be the rule, and not the exception, and then the aid of assistants of this class will be a necessity. No doubt photographers will have to be pressed into the service, failing assistants trained in lithographic work, but the former know nothing of photographic operations, and consequently would only be applied to in the event of none other being available. For these reasons we cannot help thinking that the prospects of the photographer's assistant are brightening considerably, and if he would only spend his spare time in learning something of the rudiments of chemistry, and especially of that part of the science which relates particularly to photographic reactions, he would raise his own status and that of photography at the same time. Many assistants complain of their scanty income who really are not so hardly used after all, since what they know could be acquired by any ordinary individual by three or six months' attention to work. The assistant who, as an intelligent and educated lad, enters a good studio, should, after a few years, be able to command a good salary. But he must know what is amiss with his bath when it goes wrong, how to prevent his albumenized paper from blistering, and be capable of printing a good vignette either in silver or carbon. If he can do this, and, moreover, produce a good photo-lithograph, and "pull" a Lichtdruck from gelatine without injury to the latter, he will be in a position to choose his own principal, if he has not the wherewithal to go into business for himself. A scientific man is not wanted, and indeed it is a well known fact that learned chemists are not the cleverest manipulators when they have to do with collodion plates and silver baths. Still some knowledge of chemistry is a necessity, if it only teach one to work economically, and to save the waste products. Working with such precious metals as gold and silver, it behoves one to be particularly careful of waste, and even the bichromate from carbon tissue, we were told the other day, is worth saving. Looking closely after the development drainings will, in a large establishment, result in a material addition to profits, and an economical use of paper after it has been sensitized will also make an appreciable difference in expenditure. In the case of large

printing establishments, where large pictures have to be produced for eightpence or tenpence a piece, it is, in fact, only by the exercise of rigid economy that any profit at all can be secured. Now, therefore, more than ever, it behoves assistants who desire to advance their position to study photographic manipulations from an economical aspect.

FRENCH CORRESPONDENCE.

TWO MORE COMPETITIONS AT PARIS—A NEW LENS BY VOIGTLANDER—M. ANDRA ON DRY PLATE PROCESSES—THE KEEPING QUALITIES OF CHARDON'S PLATES—PHOTOGRAPHS FROM STOCKHOLM—THE MONUMENT TO NICEPHORE NIEPCE—VISIT OF THE EMPEROR OF BRAZIL TO M. JANSSEN'S OBSERVATORY.

The French Photographic Society held its monthly meeting on Friday last, the 1st June. The president made known the programme of two new competitions which have been arranged by the Society. The first is of an international character, for a simple and practical medium to replace glass in negatives by some light and transportable tissue or pellicle. This latter is to be of such a nature as not to interfere in any way with the photographic processes in general use, whether dry or wet. The second competition is organised for the purpose of developing a means of reducing to a minimum the impediments of landscape photography, the prize being given for the simplest equipment for out-door photography. Only French photographers and makers of apparatus will be admitted to the latter competition, which will be closed, like the former one, on the 1st of January, 1878.

M. Carette exhibited to the members of the Society a new lens, constructed by M. Voigtlander et fils, to which the inventors have given the name of Euryscope. The construction of this lens is based upon the calculations of Dr. Sommer, Professor of Mathematics and Director of the Polytechnic School at Brunswick. It is composed of two achromatic symmetric glasses, in the centre of which is placed a diaphragm. The instrument is perfectly aplanatic, and, therefore, it is possible to work with a full aperture. Although for the most part designed for landscape work, it may be employed for taking reproductions, interiors, monuments, groups in the studio, &c. The authors affirm that the instrument gives straight lines, images without distortion, and that, moreover, the defect known as flare is altogether unknown. M. Carette remarked, at the same time, that a certain degree of curve being inevitable, if sharpness is desired to the very edge of the picture, this can be secured by the employment of a more or less small diaphragm. But what most of all distinguishes the instrument, said this gentleman, was its great luminous power, enabling one to secure groups in the studio in a much shorter time than usual. The instrument may be made, too, to embrace a very wide angle (from 65° to 80°), according to the nature of the diaphragm employed. At the request of M. Carette, a commission was nominated to experiment practically with the new lens.

A skilful amateur, M. Andra by name, who has made a series of experiments with the products and formulæ recommended by M. Chardon (to whom the prize for a dry plate process was recently awarded) has made known that he has in general secured satisfactory results with the same, especially when he augmented materially the time of exposure. Another operator, M. Magny, writes that having exhausted, when travelling, his stock of Taupenot plates, which he was in the habit of employing, he prepared a number of films after the manner of M. Chardon; with these he secured some very successful results, giving only half the exposure which he was accustomed to devote upon collodio-albumen plates. Finally, the jury which made the award gave some account of the keeping qualities of the plates as exemplified by those remaining in their hands ever since December, 1876. These films gave good results except that the margins were somewhat defective, a circumstance due, according to M. Davanne,

to the surrounding atmosphere, which has penetrated into the box in which these plates were confined.

M. Jaeger forwarded to the Society a magnificent collection of silver prints of various kinds, including portraits, landscapes, historical paintings, marine views, &c., all taken from the Stockholm Museum. M. Quinsac, of Toulouse, also sent some views printed in greasy ink, which had all the exquisite delicacy and brilliancy of the finest impressions produced by silver printing. These pictures, printed upon paper slightly varnished, were vastly admired.

I have spoken in one of my preceding letters of the decision of the Municipal Council of Chalons-sur-Saone, in respect to the erection of a statue to the memory of Niepce and Niepce, and their resolution to spend five thousand francs upon the monument. I have now received further details in respect to the project. M. Landa, the director of the *Progres de Saone et Loire*, and one of the Municipal Council of Chalons, in forwarding me the report on the subject, tells me that it is progressing favourably. The Executive Commission nominated by the Council is about to commence operations, and will place themselves in communication with persons who may be considered likely to further the work by means of subscription or otherwise. M. Landa, who has interested himself heart and soul in the matter, is a conscientious and zealous writer, and has represented very forcibly that the oblivion into which Niepce's name has fallen among his compatriots is anything but honourable to the nation. In England, where public recognition for services is so broad and complete towards great and useful men, people will be pained to hear that the widow of Niepce died in the hospital of Chalons, and that in the cemetery of St. Loup de Varennes, where the pair are buried, there is to-day not even a cross to mark their resting-place, which is at the present moment hidden by nettles and brambles. Let us hope that this deplorable state of things will soon be remedied.

On Saturday last the Emperor of Brazil visited the astronomical and physical observatory which M. Janssen has organized upon the terrace of the *Chateau de Meudon*, and of the establishment of which I spoke in a former letter. I had the honour of being present, and I can well bear witness to the interest taken by the august traveller in the solar images which are daily secured at the observatory, and in the magnificent instruments with which the photographs are taken. The closing arrangement, which permits one to regulate the exposure from a fiftieth to a twelfth of a second, according to circumstances, and the clock-work arrangement in connection with the heliostat, which allows the sensitive plates to remain automatically in their proper position, captivated the attention of the "Royal Corresponding Member of the Academy of Sciences," as well as the ease with which M. Janssen transformed the gigantic astronomical instruments into a photographic apparatus. My readers may know that the solar images taken at the Observatory at Meudon are not less than forty-five centimetres in diameter. They are secured upon dry plates prepared with tannin, and developed by the aid of sulphate of iron. The plates require, as we have just said, an exposure of a fraction of a second only. The visit of the Emperor of Brazil was protracted to two hours and a half, and, before leaving, he expressed to M. Janssen great satisfaction at having seen the laboratories and observatory of the eminent astronomer. Don Pedro, who starts on the 9th for Great Britain, will be in London in a few days.

ERNEST LACAN.

THE PLATINOTYPE.

BY W. E. BATHO.

THE number of processes for producing permanent photographs afford sufficient variety to suit every taste, and to meet most demands. This is one of those methods for realizing the desideratum of a permanent photograph which, while being a most elegant adaptation of the laws of chemical affinity, seems not to attract the interest it deserves.

The platinotype process of Mr. W. Willis has been set forth as a process giving a result of special value in certain departments of our art, and most decidedly the results are unique. The artist can have a photograph on any special paper with the tooth left intact for his brush work, the shades consisting of a deposit of platinum black, a substance in itself as stable as any we possess.

It is more than likely that photographers will look with some amount of suspicion on the claims made in behalf of the platinotype for permanency, when it is observed that nitrate of silver and hyposulphite of soda are generally employed in the process. Yet with equal justice might the carbon process be decried, seeing that it is possible to use fugitive colours in the making of tissue. Wherein the fading of a silver print consists a cautious chemist would hesitate in positively affirming. The usual method of picking up the symbols at random, and showing therefrom a decomposition of some sort, serves not to make matters clear. It has yet to be shown that because hypo and silver are used in the platinotype, it must needs fade.

The reactions involved in the process under discussion are very beautiful, and cannot fail to arouse more than passing interest, and is a capital example between an haphazard invention and one evidently the result of patient thought.

The rationale of the process is as follows:—*Ferrous-oxalate*, while being a good reducer of such metals as platinum, iridium, or gold, is insoluble in water, and hence there is at first some difficulty in bringing them into such a state as favour decomposition. However, a solution of the neutral oxalate of potassium is a ready solvent of the ferrous-salt, making an excellent "developer" when the salts of platinum, &c., are brought in contact therewith. *Ferric-oxalate* is readily soluble in water; it also is reduced by the action of light to the insoluble *ferrous-oxalate*, so if paper be coated with *ferric-oxalate* solution, and exposed to the light, those impressed portions will have the *ferric-salt* reduced to the *ferrous* in proportion to the light action, and be in the condition for reducing platinum or other metals upon such portions, to form a picture.

Such are the reactions involved in the platinotype. Its practice is as follows:—A starch-sized paper is floated on a six or eight-grain nitrate of silver solution. Floating is not necessary. A little of the silver solution poured on the sheet of paper, and spread with a pad of cotton-wool, I have found equally efficacious. This is allowed to dry thoroughly—indeed quite dry—before a fire, as I find this proceeding keeps the print on the surface. The silvered sheet is now placed on a plate of glass, and clipped thereto with American clips. A small quantity of a mixed solution of chloro-platinite of potassium and ferric oxalate is poured on the sheet, and spread with a pad of cotton wool, and subsequently levelled with a squeegee made of flannel wrapped round a glass rod; the sheet is now dried in the dark, and is ready for printing; it has a pale primrose colour in daylight, but rapidly darkens, being much more sensitive than silver paper. It need scarcely be added, the foregoing operations must be performed in the dark room. The printing is accomplished in the usual manner. Experience will teach when the picture is exposed sufficiently, by an inspection of the print, a faint outline only being seen. The impressed paper is taken out of the printing-frame, and floated on a hot solution of potassic oxalate, when the picture flashes out instantaneously; it is now washed in a weak solution of oxalic acid, to remove the iron salts still in the paper, then washed in water, and toned in a sulpho-cyanide bath; again washed, and fixed in a strong hypo. solution, a slight washing finishing the operations.

The permanency of the picture is assured by the entire absence of silver in the finished result. I have not, by any test I am acquainted with, found the presence of the merest trace of silver left in the paper. I believe the patentee guarantees this, yet, with all, there will be a lurking doubt in the minds of most photographers i

any method of printing wherein silver and hypo. are brought into practice. This, however, must not be allowed to tell too strongly against the platinotype method of printing, seeing that other solvents for the silver compounds can be employed, and are named by the patentee. Ammonia forms one of these, it taking the place of hypo. This I do know, that there are silver pictures fixed with ammonia which, in the course of years, have not shown the least symptom of fading. Hence it may be safely predicted that a platinotype print, when rightly produced, will have as long an existence as a print made by any other method extant. This is but my opinion, after all, and I may add, in the words of the Koran, "Wherefore let him who will, believe; and let him who will, be incredulous."

STRAY THOUGHTS ON CARBON PRINTING.

BY JOHN SMITH.*

In bringing before you this evening a few stray thoughts on carbon, or pigment printing, I may say, at the outset, that I do not bring them in the expectation that they will carry with them the weight and importance they otherwise would supposing they were uttered by a more able and experienced person in our art-science; but I simply place them before you as the result of my own thought, reading, and observation upon the subject.

In relation to the birth, rise, and progress of pigment printing, it is not my purpose this evening to say anything, except that, like numerous other very important inventions, it has had many struggles for existence during its career from the cradle to its present state of maturity.

Upon the nature of the chemical changes which take place I need not dwell, as these have often been explained in the journals and other publications, and formulæ, manipulations, and practical details frequently given. But there are points upon which there seems to be a considerable difference of opinion and practice. A few of these I will mention.

1. *The Tissue*.—Some affirm that it is not always of uniformly good quality, and, therefore, they cannot get uniformly good results; others say the fault is not in the tissue but in the operator, the tissue being always good and reliable. Again, the Autotype Company claim to have the sole right to make and sell the pigmented paper, while some persons affirm that anyone has a right to make it for himself. Some say that the tissue sold by the Autotype Company to licencees and to those who have no license is all alike, but the Company deny the charge. These matters of difference, I presume, we shall not be able to settle here to-night, but shall have to leave them for settlement by actual experiment or by some legal tribunal, as the case may be.

2. *The Sensitizing Bath*.—Upon the strength or percentage of bichromate salt to be used various opinions are held. To take a few: Mr. John Milner (see *British Journal Almanac*, 1877, p. 73), after stating some of his difficulties, says:—"The result was the adoption of a one and a-quarter per cent. bath for all carbon work, large or small—prints up to twenty by sixteen leaving nothing to be desired so far as the strength of sensitizer was concerned." The Autotype Company give strengths of five, four, and three and a-half per cent., while some others give as high as seven per cent. As to the composition of the bath: some advise the use of bichromate of potash simply; others, the same with a few drops of liquid ammonia added until a pale yellow colour is produced. Some advise a mixture of the two salts, bichromate of potash and ammonia. Mr. R. Jastrzembaki gives.

Bichromate of potash	4 parts
Carbonate of soda	1 part
Water	100 parts

One class recommend the addition of alcohol to the bath,

* Read before the West Riding of Yorkshire Photographic Society.

M. Charente going as far as forty per cent. Another class of persons say that, after sensitizing, the tissue should be passed into a bath of alcohol.

Again; if we advance a step further we meet with the same difference of opinion with respect to the time of immersion. Some operators have advised a very short immersion—only six seconds—while some others advise as much as three minutes. Some draw the tissue out of the bath over a glass rod in order to take away part of the bichromate solution; others advise that it should be placed, face down, on glass, and take away the excess by the use of the squeegee, then strip off from the glass, and suspend to dry; while some prefer drying on the glass, and claim the double advantage of smoothness of surface to lay on the negative, and better keeping qualities.

As to drying, we have various methods. By one the tissue is placed with its back on a piece of blotting-paper, over a stick or rod, allowing the ends to slope from the middle. A second will hang up the tissue in an open room by means of clips—by preference near an open chimney. A third will dry in a closed box, through which a current of cold air is made to pass. A fourth will employ a gentle heat, and so on. Again: it is stated that the drying must be done slowly, and thereby obtain a greater degree of sensitiveness and freedom from reticulation. Others state that drying may be done quickly, and affirm that no reticulation is produced thereby.

I will now glance at the preparation for printing. If the object be simply to get a print from any negative in permanent colours, then the only thing requiring to be done is to put a strip of paper over the face of the negative close to the edge, to partly protect the sensitized tissue from the action of light, and print for the required time; this will vary according to the negative used. But if any particular shape, such as oval, cushion, &c., be required, then there are three ways by which the artist may obtain such results:—

1. By the method long used in silver printing—viz., masking the negative while the picture is being printed, and afterwards tinting the margin, by exposing it to light, while the printed part is covered up with a blank mask. For carrying out this method in pigment printing, specially prepared frames are required in order to get accurate registration of tint with the print. M. Lambert has a patent for frames for this purpose; Mr. G. Higginson, of Southport, advertises some special frame; and, after much thought and labour, Mr. Greaves and myself have devised what we think to be a very great improvement on both, and by the use of which much time and printing space are saved. Two of these improved frames are here for your inspection this evening.

2. This may be accomplished by placing a mask of the desired shape in the dark slide or other part of the camera, which mask is brought very near the sensitive plate; and thus the negative is taken of the proper or desired shape, leaving all the margin of clear glass. After varnishing, a mask of uniform texture, and of such a degree of opacity as will give the required tint of margin, is placed on the negative, the opening of which exactly coincides with the figure on the plate, and from such prepared negative, pictures may be printed and tinted at one operation.

3. By having two masks carried in two swing-frames within the camera—one carrying the mask for the figure, and the other the mask for the tint—a negative can be taken from which prints may be made with tinted borders at one operation. This last method is the subject of a patent, though I may say that months before the patent was taken out I named the method to Mr. Greaves, of Halifax.

The vignetting and tinting on pigment tissue has been found to be attended with very considerable difficulty, because the operator cannot see the progress of the printing. Mr. Witcombe, in an article which he contributed to the YEAR-BOOK OF PHOTOGRAPHY for this year, describes a method by which he produces vignettes.

What success has attended his labours I am not in a position to say; but I think I can say with safety that Mr. Greaves, after much patient thought and experiment, has at length succeeded in producing tinted vignettes in carbon which are perfect gems of art, and which leave nothing more to be desired.

After printing there seems to be a variety of modes of procedure in preparing the temporary support. Some wax with fluid and others with solid wax. Some use one collodion, and others a different one.

After mounting on the temporary support there is again a divergence. One artist says the prints must not be allowed to remain under pressure more than two minutes; then place in warm water—not hot—and the paper will strip off very easily. A second says the print should be under pressure for half-an-hour at least.

After development one advises the putting on of the transfer paper while still wet, while another advises drying first, and then wetting with cold water before it is put on. And so on, through every stage of the work, I might point out very wide differences in practice; but I refrain from going further, as I feel that I have already taken up too much of your time by these random remarks. Before concluding, however, I should like to give my opinion as to what I think would be good practice, especially for amateurs.

The tissue should be good in quality and of colour to suit the taste; it should be kept in a cool but dry place, and must not be allowed to become hard or brittle. It should be always as flexible as patent leather. I would sensitize in a weak bath of from one and a-half to two per cent. strength, and if acid neutralise with carbonate of soda, adding a few drops of glycerine to each pint of water. I should give a complete immersion, and for such time as would be needful to wholly saturate the tissue, thus getting more uniform sensitizing.

I should then take the tissue out of the bath, and place it, face downwards, on a glass plate previously prepared, as recommended by Mr. Milner, by giving a slight coating of Castile soap (two grains to one ounce of methylated alcohol), after the manner of waxing a plate, and let it dry on the glass. If dried quickly, and the glasses placed one upon another, so as to protect the tissue from the air, it will keep good for many weeks.

In waxing I should wax the plate by preference with solid bees'-wax, warming the plate, then make a few marks across the wax, and while still warm polish off with flannel.

I should next coat with plain, thin, tough collodion—pyroxyline two grains to the ounce of solvents—using as much alcohol as possible, to prevent the waxing from being dissolved, and thus ensure easy stripping. The transfer paper should be well softened and carefully applied. After getting about half dry, put on the cardboard (which has been previously damped) with thin glue, and dry by placing in a strong current of warm air. In a few hours the prints will strip off perfectly, and have a surface of the same character as the glass from which they are taken.

I have brought with me for your inspection and adoption, if you think there is any value in them,—

1. A model of an apparatus for sensitising the tissue. This, as you will perceive, is a box carrying a number of rollers, around which an endless web is carried. The

tissue is placed upon and attached to it, and then turned round, bringing the tissue into the bath, at the same time keeping it straight (without having to place the hands in the poisonous solution) until fully sensitised. From what we read of the damaging effects upon the health of the operator, I think some such method be used.

2. A drying-box, or chamber, divided by a number of

partitions, which are alternately short at the top and bottom, thus making, when the door is closed, a continuous passage from the inlet to the outlet; and an

induced current is made, either by burning gas within an iron chimney placed over one of the divisions of the box, from which there is an opening into the chimney, or by placing a small fan over the same opening, and worked by some mechanical power—by preference a small tubing water-wheel—by this means drawing a powerful current of cold air through the box, and thus drying the tissue in a short time. This same arrangement may be made use of to dry the newly-developed plates, and also after mounting on cardboards.

Thanking you for your patient attention to my stray thoughts, I hope that our meeting may not be altogether profitless.

ANOTHER METHOD OF WORKING THE GELATINE PROCESS.

BY H. HOULGRAVE.*

I HAVE devised the following method for working the gelatine process in the hope that it may suit the convenience of those who are not able to devote any time during the middle of the day to making emulsions. The formula with which I have been most successful is that published by Mr. J. King, namely.—

Nelson's opaque gelatine	...	40	grains
Bromide of potassium	...	40	"
Nitrate of silver	...	56½	"
Water	...	2½	ounces.

In making the emulsion, proceed as follows:—At about nine a.m., or any convenient time in the morning, weigh out, as carefully as possible, the bromide, and put it into a teacup or other similar vessel, pouring on it about one ounce of water. I then add the gelatine, cover up the cup to keep out dust, and leave it without any further care till five or six o'clock in the evening, or later if more convenient. The gelatine must now be dissolved, and the emulsion made. To effect this, place the cup, a small glass beaker (in which has been previously dissolved the silver in about six drachms of distilled water), and a suitable bottle, in a shallow tin dish half filled with cold water, and supported on a retort stand above a Bunsen's burner, which is now lighted. Having allowed about ten minutes for the materials to get thoroughly warm, pour the silver into the gelatine, stirring briskly all the time, and for about a minute longer. Then transfer the emulsion from the cup to the beaker, and thence to the bottle, rinsing out the cup and beaker with a little water, which is also added to the emulsion, and then shake up most thoroughly for two or three minutes. The emulsion must now be kept warm by any convenient means for a few hours. At about ten p.m. pour it into a flat porcelain dish seven inches by five inches, and leave it the whole of the night to set. Next morning, plunge the dish into cold water in a mug sufficiently large to contain it, cover it up from the light,

and there let it remain the whole of the day. At about six p.m. change the water, and let the emulsion remain in it an hour or two longer, then drain it for a short time; it is now ready to be dissolved and filtered previous to coating the plates.

The most convenient way of doing this is to pour a little water into the tin dish, on the top of which dish is placed that containing the emulsion (but not in the water); light the Bunsen's burner, when the hot steam which rises will very soon effect the solution of the emulsion, which should then be filtered through a bit of sponge. Then proceed at once to coat the plates in the manner so often described before.

After allowing the emulsion which remains to set in the bottle, I have been in the habit of pouring a little strong alcohol on the surface, hoping that it would thus keep indefinitely, and would be always ready for use by simply pouring off the spirit, and then remelting; but in this I have been disappointed. I find that after it has been warmed up two or three times, the gelatine seems to lose in a great measure its power of setting, the emulsion becomes very thin, and the film made with it falls up during development in a very curious manner. I am in hopes that a little fresh gelatine will remedy this defect, but have not yet had sufficient time to investigate this matter thoroughly. I will now say a few words on the prevention of blisters, which are the bane of the gelatine process.

Before proceeding to develop, flow over the plate a little common methylated alcohol; then wash off thoroughly by placing the plate in a dish and changing the water three or four times. Since adopting this simple precaution I have never seen a blister. At first I used a little pyrogallie acid dissolved in the alcohol, but now find that this addition is neither necessary nor useful.

I generally use the developer recommended by Mr. R. Kennett, but do not find any very material difference between developing a gelatine and a collodio-bromide plate. The gelatine plates, however, often lose excessively in the fixing bath, and, in consequence, require strengthening up a little subsequently. This I never attempt to do till after the negative is dry, when I re-moisten it with spirit, wash, and then apply the usual acid silver and pyrogallie solutions, with which I can get any amount of density, the difficulty being to know exactly when to stop.

There is one thing I have omitted in the proper place, and that is, in the hope of making the emulsion keep better, I have thought it desirable to increase the proportion of gelatine in the above formula from forty to fifty grains. And now, in conclusion, allow me one word of apology for the negatives shown. I beg you will not look upon them as finished productions, but as purely experimental ones—indeed, almost first attempts. Still I think they are sufficiently varied to show the capabilities of the process.

LOST ART. —We have received from Mr. B. Davison, of Odin, Ill., a small book, bearing on its cover the following title:—"Instructions for Oil Paintings on Glass, consisting of Lost Art, Crystal or Oriental, Diaphane Celestial and Italian and improved Grecian Oil Painting, by Mrs. Ann B. Davison, Practical Artist, Galesburg, Ill. Entered according to Act of Congress, &c., in the year 1869." We extract the following portions:—"Lesson 3: Lay your picture in clean water a few moments, until the paper is wet through, &c.; then varnish your glass well, &c. Then lay your picture face a de up and hold your glass varnished side down, and lay it down carefully (upon the picture) and press lightly; this will unite them." These instructions are given for pressing out air-bubbles. The work further says: "The air being all removed, leave it until well dried to the glass, &c. Then wet the picture on the back with water and rub it with your fingers until the paper is all removed but a light film, which the print retains. This you must be careful not to break. Then let it dry fifteen or twenty minutes; then varnish it again with crystal varnish. This will make it clear and transparent." It is unnecessary for us to make any comment on the above.—Ed. *Anthony's Bulletin*.

* Read before the Liverpool Amateur Photographic Association.

thread for thread. I have often had the doubtful honour of having my pictures appropriated by painters, and do not object to artists refreshing their recollection of nature by looking at my photographs, but I strongly object to wholesale copying. One of the most impudent cases of such copying occurs in the last Exhibition of the Dudley Gallery. The following correspondence on the subject may, perhaps, interest your readers.

Tunbridge Wells, May 28th.

H. P. ROBINSON.

Tunbridge Wells, February 2nd, 1877.

To the Secretary of the Dudley Gallery.

SIR,—I mentioned to you yesterday that a copy of one of my pictures was exhibited in your gallery as the work of another artist, and under a different name to that which I had given it. The number of the copy in the catalogue is 136. My picture, of which I enclose a rough copy, is copyright; and I could obtain redress under the Copyright Act; but I should prefer not to go to that extreme length, and therefore ask you to bring the facts under the notice of the Committee.

It will be seen, on comparison, that Mr. Macbeth has omitted the sky, and added some boats; the rest of the picture is identical with mine, and could not have been an accidental resemblance.

The injustice of this appropriation of my property will be more clearly seen if we reverse the position. Suppose, for instance, I obtained possession of one of the best pictures of the year, and took a photograph of it, and then sent the photograph to an exhibition, claiming the composition, light and shade, and invention as my own, and tried to sell it: what would all honest men be entitled to call me? The cases are exactly parallel.

I have also to submit that to send a copy for exhibition in the Dudley Gallery is to endeavour to impose upon the Committee, and that in this case it has succeeded.—I am, sir, yours obediently,
R. F. McNair, Esq.

H. P. ROBINSON.

February 3rd, 1877.

SIR,—I beg to acknowledge the receipt of your letter and enclosure of the 2nd inst., and, in reply, to inform you that they will be duly laid before the Committee at their next meeting.—I am, yours obediently,
H. P. ROBINSON, Esq.

R. F. McNair, Sec.

To the Treasurer of the Dudley Gallery.

Tunbridge Wells, April 25th, 1877.

SIR,—I beg to call your attention to the enclosed copy of a letter which I sent to Mr. McNair on the 2nd of last February.

In reply, Mr. McNair informed me that it would be laid before the Committee at their next meeting. I have waited nearly three months, and have received no further communication from your Secretary, from which I can only infer that either Mr. McNair has suppressed my letter, or the Committee have no objection to countenance a gross injustice and imposition, which I cannot believe.

I take the liberty of writing to you as the only official besides Mr. McNair whose name is given in the catalogue.

I enclose a rough print of my picture, which I should be obliged if you would compare with Mr. Macbeth's (No. 136).—I am, sir, yours obediently,
H. P. ROBINSON.

Edward Hamilton, Esq., M.D.

9, Portugal Street, Grosvenor Square, April 30th, 1877.

SIR,—I beg to acknowledge the receipt of your letter and enclosure of photograph, &c.

Mr. McNair did not suppress your letter of February 2nd.

I cannot myself see on what grounds your letter is to be brought before the Committee.

Your grievance, if you have any, is with the artist who you say has copied your picture.

How was the Committee to know that the drawing of Mr. Macbeth's was a copy of yours? And surely you can hardly suppose that after the Exhibition has been opened to the public, the catalogue printed and published, the Exhibition was to be altered and deranged, and a fresh catalogue printed, because you think an artist has copied your photograph.

I should be glad to know what your complaint against the Committee consists of, so that I may be able to bring something definite before them.—I am, sir, your obedient servant,
H. P. ROBINSON, Esq.

EDWARD HAMILTON.

Tunbridge Wells, May 5th, 1877.

SIR,—Absence from home must be my excuse for not replying to your letter before.

I pointed out in my letter to your Secretary that a copy of one

of my pictures had been sent to your Exhibition as an original picture. I asked to have my complaint placed before the Committee. It was not for me to dictate to the Committee what they should do to vindicate the honour of their Exhibition. I knew there were gentlemen on your Committee who would not countenance a theft disguised under any circumstances whatever, but I expected that the artist who had perpetrated the imposition might possibly have been warned that in future he must not break your rule that no copy be sent for exhibition. I expected that as the drawing was in some sense an attempt at a fraud, it would have been withdrawn from sale, if not from exhibition. I expected that your Secretary would fulfil his promise, and place my letter before the Committee, which was not done.

I have no complaint against the Committee. The Committee has had no opportunity of doing me justice, or the reverse, not having had my letter before them. I am sorry I cannot get my letter under the consideration of the Committee, but my purpose will be nearly as well served, if not so pleasantly, by the publication of this correspondence for the guidance of photographers in similar cases where their thoughts and designs are "conveyed" in a like unblushing manner.—I am, sir, yours obediently,
H. P. ROBINSON.

Edward Hamilton, Esq., M.D.

Dudley Gallery, May 8th, 1877.

SIR,—I beg to inform you that your correspondence was this day laid before the Committee, and to state that no meeting of the Committee has been held since the opening of the gallery, until quite recently, and, therefore, that your letter had appeared to be neglected.

The Committee regret that there should be any appearance of plagiarism on the part of the artist to whom you refer; but they consider that the matter rests entirely between the artist and yourself.—I am, yours obediently,
H. P. ROBINSON, Esq.

ROBERT MCNAIR.

To the Exhibitor of the Copy.

Tunbridge Wells, May 9th, 1877.

SIR,—In the Dudley Gallery is a drawing (No. 136) to which your name is attached in the catalogue. This picture is a direct copy of one of my photographs. I have had a correspondence with the Secretary and Treasurer of the Gallery on the subject of this misappropriation of my property, which correspondence I am about to publish; but before doing so, I think it only just to give you an opportunity of explaining, if you can, why you have copied my picture, and why you call it your own, seeing that the design, invention, composition, and light and shade, are mine. I may add that the photograph is my registered copyright.—I am, sir, yours obediently,
H. P. ROBINSON.

James Macbeth, Esq.

23, Newman Street, Oxford Street, London, W., May 10th, 1877.

SIR,—I am obliged by your letter, which gives me an opportunity of clearing myself from the charge of infringing your copyright. I saw the photograph in the house of a friend. I borrowed it to assist me in some of the minor details of the water in the drawing you complain of, supposing it was a photograph from nature done for the use of artists, who are, as a rule, the only buyers and appreciators of such works. Had I known that the design, invention, composition, and light and shade were your own, I should have no more thought of using it than I should think of copying a picture by a brother painter.

The Secretary and Treasurer of the Dudley Gallery are in no way accountable for the matter, and the publication of your correspondence with them would serve no good purpose. If you like to publish this letter you are at liberty to do so.—I am, sir, yours truly,
J. MACBETH.

Mr. H. P. Robinson, Tunbridge Wells.

Tunbridge Wells, May 22nd, 1877.

SIR,—In reply to yours of the 10th, allow me to say that the mistake you and some other artists make is, that photographs are as much open to you to copy as nature herself, just as if they were taken by chance and were common property; whereas the best photographs are almost, if not quite, as much the result of artistic design as paintings.

As to you having borrowed "minor details," only a glance at the two pictures would convince anyone that the sea is copied in every detail as nearly as you could do it. Suppose a dozen painters had copied the same photograph, whose would have been the original picture? It is a fact that I intended to make a painting based on the photograph of mine you copied. If I fulfilled my intention, and sent the picture for exhibition, it would be said at once that

my painting was a copy of your drawing, just as if I had stolen your sketch, from nature, of the subject, and copied it.

There is a purpose to serve in publishing the correspondence which you do not seem to see. It would serve to make known to painters a fact of which some of them do not appear to be fully aware, which is, that there is as much property in a photograph as in a painting, and that it should not be appropriated without permission. I do not object to painters taking hints and suggestions from my pictures, just as they may from the works of artists in other materials; but I do object to your sending a copy of my picture to an exhibition, and calling it your own.—I am, sir, yours obediently.

H. P. ROBINSON.

James Macbeth, Esq.

MAGIC LANTERN AS AN AID TO INSTRUCTION.

SIR,—The present season of the year may not strike you as the most suitable for a paper on the magic lantern, but there is this to be said in its favour—that the makers are now laying in stock for the next winter, and hence they are in a good position for adopting any improvements which may be suggested.

I must begin my letter by expressing the obligations I am under to Mr. S. Hightley, for his valuable articles on the lantern in the fourth volume of "Casell's Technical Educator." They have added much to my stock of knowledge on the subject, both in the theory and practice. As an instance of the former, I may mention his remarks on the symmetrical condenser now so much in use; and of the latter, the hint which he gives for steadying the jet and lime-holder by fling away the supporting rod on the side opposite to the screw. This simple plan is so effectual for the object designed, that it ought to be generally known and adopted.

I have long used the lantern for educational purposes, and have recommended it to my brother clergy. The difficulty with many, however, has been that they cannot obtain coal gas, and they find the oxy-calcium process with spirits of wine not easy to manage.

Mr. S. Hightley, in his paper before referred to, describes an oxy-spirit lamp which seems perfect in all its arrangements, but I have never met with one of that construction. The lamp which I have seen is an ordinary fountain lamp, and in this form the light is apt to fail when the lantern is tilted upwards. My own plan has been to work with Pumphrey's Vaporiser, when I cannot get coal gas. It is an inexpensive apparatus, and can be used with any lantern, the spirits being volatilized, and burnt without a wick at the mouth of an ordinary safety jet. There are, however, two or three points to be observed in order to ensure success.

Much depends upon the construction of the burner. If you use an oxygen nozzle with a very small bore, and force the gas through it by strong pressure—say fifty-six pounds or more on the bag—there will be a dark nucleus in the centre of the incandescent lime spot, supposing the cylinder of lime to be somewhat near to the orifice of the jet. And not only so, but on looking into the anterior glass of the lens from the front, you will see the same dark centre, with a ring of light surrounding it, something like an annular eclipse of the sun. The explanation is that the two gases are travelling at so different a rate at the time of their emergence from the jet, that they do not mix properly, and hence there is an excess of oxygen in the middle of the flame, producing a cooling effect.

I have heard it said that the greater the pressure on the gas-bag in the oxy-calcium process, the better the light; but in my own practice I find quite the reverse, and have obtained the best results by using a low pressure not exceeding twenty-eight pounds. The oxygen then travels slowly, and mixes more thoroughly with the spirit vapour before the flame touches the lime. Quantity of oxygen, however, is important, and hence I enlarge the bore to one-twentieth of an inch, to compensate for the diminished pressure. A single trial will show the advantage

of this enlargement of the bore, the light being better and more steady, whilst the lime requires to be turned seldom, or not at all.

Look at the matter from a common sense point of view. In this oxy-calcium process you have spirit or benzoline vapour escaping slowly through a large orifice of a quarter of an inch in diameter, and you send a small and rapid stream of oxygen into the centre of it. Unless, therefore, the lime cylinder be at some distance, the two gases cannot mix. When, however, you use a larger stream, and one whose rate of travelling corresponds more nearly with that of the spirit, the admixture is perfect: and complete combustion is the result. At all events, whatever the theory may be, there is no doubt that in practice the latter method gives the best result.

I have mentioned one-twentieth of an inch as a useful size for the oxygen orifice; but I may be asked, how is the hole to be measured by an amateur without the proper appliances? It may be done sufficiently nearly by stamping it on a sheet of paper, and making five impressions, side by side, which ought then to measure a quarter of an inch; or by picking out a stocking-needle which exactly fits into the bore, and pricking a few holes on paper close together.

Having very little spare time at my disposal, and finding the process to work well, I did not experiment in the direction of altering the size of the exterior spirit orifice, which, in my instrument, measures a quarter of an inch across; but I believe it would be an advantage to make it smaller. This would economise the spirit, and, as there is a *vis a tergo* in the shape of a lamp boiling the spirit at the other end, it would give increased force to the stream of vapour, and so improve the light.

Mr. David Young, of Manchester, sent me, some time since, a burner which he names "the economic jet," and I found the light given by it in the ordinary blow-through process to be remarkably good. I allude to it now because the mouth of the hydrogen tube was much contracted, measuring, possibly, not more than one-eighth of an inch across. This jet, however, did not, in my hands, answer with the spirit vaporiser, as there was a strong whistling or humming noise, which I could not overcome except by reducing the pressure on the oxygen until it was too low to give the requisite amount of light. The jet was not convertible, or I would have removed the oxygen nipple, and inserted one with a larger bore, which I doubt not would have made the flame quite noiseless.

I noticed, further, in Mr. Young's jet, that the oxygen orifice was below that of the hydrogen; whereas in the common mode of construction the oxygen pipe projects above the other, and passes into the flame. These small points are not by any means unimportant, but should be carefully studied, with reference to the particular process to be employed. A suitable burner is as necessary, in its way, as a good condenser, and the makers have now a leisure time in which they can prepare for the next season. An interchangeable jet, with spare nozzles to screw on as required, is, in my opinion, the most useful form: some with large holes to use in the single lantern, with low pressure, and others with smaller holes for the binomial lantern, when the flame is to be turned down to the blue; the large bore will allow the flame to pass back (in the oxyhydrogen process) unless it be kept at the full height, which would disturb the lecturer, although unattended with danger.

One remark more, and I will close my letter, which has already exceeded the limits assigned to it. A beginner will perhaps find a difficulty in centering the jet in the lantern when it is heated by the small lamps employed with Pumphrey's vaporiser. To avoid this, let him cut a circle of paper the size of the condenser, with a small hole in the middle, and stick it on the back glass with a wafer. He will then see exactly the height at which the jet should be fixed to bring the lime spot on a line with the optical

axis, and it will remain only to cut a half cork, or a piece of soft wood, and tie it, underneath, on to the supporting pillar, so that for the future the jet may be dropped on to it, and screwed up securely.

I have mentioned already that I work the oxycalcium process with the lime cylinder rather near to the jet, although not quite so near as in the oxyhydrogen process. In all comparative experiments the distance from the jet should be noted, as it has an influence upon the result. I may add that the *soft* limes are preferable to the hard when low pressure is to be employed.—Believe me to be, yours faithfully, T. FREDERICK HARDWICH, Formerly Demonstrator of Chemistry and Lecturer on Photography in King's College, London.

THE NITRATE BATH.

DEAR SIR,—The bath defects described in the article in last week's News by W. K. Hosken answer very much to those I treated in an article I sent to the YEAR-BOOK of 1876; and if he finds the new bath go the same way after a short period, he had better look to the distilled water he may be using for the source of the annoyance. When these fine lines make their appearance, the bath in all other respects works beautifully, and keeps good. I always find it rather overcharged with nitric acid, and nothing seems to cure it but first making it alkaline, then reducing to dryness, fusing, and making up again with pure water. Ordinary water, with a little permanganate of potash added, and also a little silver, and then passed through the filter, answers well. As these lines always appear in the hottest weather, these few words may prove reasonable.

I have something to say on Rembrandt lighting and retouching, but leave this for the present.—Yours truly, S. Cheapside, E.C. GEO. HOOPER.

PORTABLE STUDIO.

DEAR SIR,—Seeing in your last edition a correspondent "W. H. M." wishing to receive some information as to the erection of a portable photographic studio, I have much pleasure in forwarding a copy from the plans of a studio I erected three years ago for my brother, who was going to commence business in Australasia, and he being a lover of perfection in all things, thought he might encounter some little difficulty in getting joiners sufficiently skilled to undertake the erection of a good photographic studio; and to meet this want no expense was spared to make his outfit complete. The studio in question was erected at a cost of £200. Exclusive of furniture and fittings, it is thirty feet long by fourteen feet wide, with one large side-light which is always placed to face the north; the side glass is six feet high, and that of the roof

Frame work of studio.

DESCRIPTION OF PLANS.

18A, frame work of studio, showing joints, screw bolts, &c.; V8, ventilators; 13C, beam showing the joints and screws; 14B, beam showing iron plates.

Floor of studio, 40 feet long by 14 feet wide.

fourteen feet long, and made in sashes five feet wide; the length of the centre pole is fourteen feet high, and eight

inches square; the back pole is twelve feet long and eight inches square, and has two feet slope of roof at the back, and the glass side has a slope of eight feet, which does not give it the slightest opportunity of leakage in the wet test weather, a fact which cannot be too highly estimated in a good photographic studio.

The dark portion is made in panelled sashes of not more than five feet wide and high, according to the portion it belongs. The supporting beams are forty feet long in all, the dark room being placed at the end, and also a printing and painting room; but these beams can be divided into three by means of screw bolts and iron plates. The cross poles fit into sockets, and are bolted in like manner to the rest, and when these joints are screwed up they are firmer than if they were all in one piece, and the whole may be taken down or put up in two hours by the aid of two men,

14, stove; 10, backgrounds; 12, glass side; 11, door; 9, passage; 8, painting room; 16, printing room; 13, dark room.

and forms one of the most elegant, comfortable, and healthy studios a photographer could wish to work under. It is fitted with a set of spring blinds, also a set of velvet curtains, lined with black twill, which will allow it to be shut in complete darkness if required. The glass sashes can also be shut in by means of sliding shutters to prevent being broken when out of use.

It is heated by two of Alexander and Allan and Co's oil stoves, which are very portable, and give the required amount of heat without dirt and attention of a coal or coke stove. It is a great annoyance—especially when you

Beam work, showing the joints, iron bolts, &c.

are busy with some very important personage—for the boy to come and mend the fire, and create a dust, or let a little smoke escape when closing the door of the stove; for, strange to say, the smallest portion of dirt or smoke can always find its way to the dark room.

I think I have given you all the information necessary to explain the structure of the portable studio; but if I have not been definite in detail, I shall be most happy to supply any further matter that may be required, either by letter, or in the PHOTOGRAPHIC NEWS.—I am, dear sir, yours, &c., JAMES H. CORSCADEN.

OXYGEN GENERATING APPARATUS.

DEAR SIR,—Yesterday my attention was drawn to an article in your issue of May 25th, entitled "Another Improvement in Making Oxygen," by Mr. David Young; and at the same time Mr. David Young's specification of patent was placed in my hands. I was rather surprised to find that Mr. Young had taken out a patent for an oxygen generating apparatus which has many years ago and very often since been made and sold by myself, and now is and has been in constant and general use. So near are Mr. Young's specification, his drawing, and description of the apparatus, to that

which I have so long since made, that one might imagine that he surely must have seen and copied it almost to the letter.

I do not claim any originality of invention, as that, so far as I know, belongs to one of a very large firm of manufacturing chemists in Manchester, viz., John Dale, Esq., Messrs. Roberts, Dale, and Co., Cornbrook Chemical Works. The apparatus consists of a retort, with a flange as marked 25 in Mr. Young's specification, with a clip as marked 26, which by means of a screw, 31, tightens a cover, 27, upon the end of the retort. Again, one thing which Mr. Young seems to consider new and very important, viz., the thin tube, as claimed by him in his specification, lines 42 and 43, page 3, for holding the charges of oxygen mixture, however important it may or may not be, is not new, for the reason that the retorts in question, which I have so long since made, have all got thin and separate loose interior tubes for holding the oxygen mixture.

Now, in justice to your readers, I think it only proper to make the above known, so that they need not pay heavy and exorbitant prices to "would-be patentees" for apparatus, when there is not the slightest occasion so to do.

I also notice that Mr. Young has given a sketch of a vertical oxygen generator, which he does not seem to approve. I am not surprised at this, nor would I be surprised if your readers disapproved of it as he has described and drawn it. It looks to me as if he had been making a very vile attempt to imitate another person's oxygen generator, a description of which has been already published.—Yours truly,

JOHN CHADWICK,

Engineer, and an Old Amateur Photographer.

Princes Bridge Iron Works, Manchester, June 5th.

SIMPLE AND EFFICIENT DROPPING BOTTLE.

SIR.—In your last issue you gave a sketch for one of the above. Will you allow me to add another for ordinary dark room work. Flatten the glass stopper of the ordinary iodising bottle usually sent out with collodion pints—on two sides, either on a grindstone or rubbing on a flagstone—about the sixteenth of an inch; replace the stopper; the air being admitted through one side, the solution will drop to a nicety through the other. For travelling, temporarily substitute a cork; or, when you can insure your chemicals not being turned upside down, there will be no leakage if the bottle is not more than half full.—Yours obediently,

WILLIAM BALL.

Proceedings of Societies.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this Association was held on Thursday, the 31st ult., at the Free Library, William Brown Street, the Rev. H. J. PALMER, President, in the chair.

The minutes of the previous meeting having been read and passed, some discussion ensued on the difficulties of arranging the excursions so that a larger number of members might be able to avail themselves of them. Nothing definite, however, was arrived at except that it was thought advisable to join the Liverpool Naturalists' Field Club on their various excursions.

The SECRETARY then read a communication from Mr. H. Houlgrave on "Another Method of Working the Gelatine Process" (see page 268). The paper was illustrated by a number of excellent negatives, of various subjects, taken by the process. In the discussion which followed, the Secretary described the various apparatus which Mr. Houlgrave was in the habit of using.

The PRESIDENT said that the members would remember some specimens which he had shown them at a former meeting of the curious effect some gelatine films had upon stripping the dry films from the glass—namely, that the films brought away flakes of glass, making both films and glass useless. He had now to show an ordinary porcelain dish, in which some gelatine emulsion had been left to dry. The emulsion had wrinkled up, bringing with it most of the glass of the porcelain in a most curious

manner. The only way he could account for it was the contraction of the gelatine, owing to too high a temperature in drying, as the dish had not been exposed to light in a manner similar to the glass plates. He (the President) believed excessive temperature would be found the great terror of gelatine workers, for many of his failures were solely owing to heat in making his emulsions and plates.

The SECRETARY observed that Mr. Houlgrave also found that to be the case, his difficulty being to get a very slight heat without the danger of its failing or increasing during his absence. Mr. Houlgrave now used a small spirit lamp, which was perfectly successful. This lamp he had made by inserting a piece of glass tube through the cork of an ounce bottle containing methylated spirit. The tube should be just large enough to hold one thread of cotton wick. A small hole drilled in the top of the bottle admitted air as the spirit became exhausted. Though the flame was so tiny it gave out all the heat that was required, and burned for eight hours with a regularity he was unable to obtain with night-lights, gas, or other means.

Mr. J. H. T. ELLERSON recommended the use of sponge lamps, which would burn two or three days with as small a flame as might be needed.

Mr. W. H. KIRBY said it had been suggested to him to try the effect of steeping a collodio-emulsion plate in beer previous to developing. He produced a plate, half of which had been treated in that way, the other half without. The treated half was a good negative, but the beer had made the film so insensitive where it had been used that only a weak positive could be obtained.

Some views of the wreck of the steamer "Dakota," taken by Mr. W. King, on commercial plates, were exhibited. They were examined with interest; but as negatives they were valueless, being completely covered with opaque spots, evidently the fault of the manufacturer of the plates.

It was proposed that the monthly meetings should be held in July and August, instead of omitting them as heretofore. The decision on this point was postponed till the following meeting.

The meeting was shortly afterwards adjourned until the 29th instant.

FRENCH PHOTOGRAPHIC SOCIETY.

A MEETING of this Society was held on the 4th May, M. PELICOT (of the Institute) in the chair.

The PRESIDENT communicated to the Society the circumstance that by order of the Minister of Public Instruction, M. Chardon (to whom the dry plate prize was recently awarded) had been named an Associate of the Academy.

M. DAVANNE read a letter from the director of the Kew Observatory, thanking the Society for the medal awarded in connection with the last exhibition.

A letter was also read from the Minister of Public Instruction, acknowledging receipt of medals to officers connected with his department, and complimenting the Society on the work of progress on which it has been engaged.

M. DAVANNE said that the Minister had placed a further sum of five hundred francs at the disposal of the Society for a new prize.

It was resolved that the award should be made for improvements in travelling apparatus, and MM. Davanne, Ferrier, et Harrison were desired to draw up a programme in reference to such competition.

It was further resolved that a silver medal should be given with a view to encourage the employment of emulsions and dry plates, the award to be given for a means of completely suppressing glass plates, and replacing them with a thin, supple, light, and unbreakable film.

M. PERROT DE CHAUMOUX called attention to the foreign journals, and some articles of importance in the Year-Book and elsewhere. M. Perrot also called attention to the so-called reticulation in carbon printing. He adduced the opinion of Mr. Baden Pritchard upon the subject, and quoted the recommendation of Mr. Anthony to add five per cent. of glycerine to the sensitizing bath to obviate the defect. M. Jeuneaud advised addition of the same material some years ago.

M. BZALE stated that a good paraffine lamp gave as good results as the Drummond light, while at the same time the former was much easier to manipulate.

The lead intensifying process of MM. Eder et Toth was brought before the Society.

M. A. MARTIN presented the Society with a memoir on "Methods employed to determine the curves of lenses," accompanied by tables to assist in the calculation.

M. TERPEREAU also presented the Society with a pamphlet entitled "The misfortunes of an amateur photographer."

M. COMTE exhibited an apparatus for filtering collodion. It was a vessel provided with two openings, one for the introduction of the funnel in which the collodion to be filtered is introduced, the other having fitted to it an India-rubber bulb. By pressing the latter, the air in the vessel is exhausted, and consequently the collodion in the funnel runs down with increased velocity, since a vacuum is caused, and the atmospheric pressure acts upon the liquid collodion. In this way the filtration of collodion, which is otherwise a very slow operation, is considerably accelerated.

M. DAVANNE complained that the vulcanized rubber corks employed in the filter apparatus were to be avoided; the ether and alcohol attacked the sulphur contained in the rubber and caused trouble. He advised the use of good cork.

M. MARTIN said that if the vulcanized rubber were boiled in an alkaline solution it would be devulcanized, and thus rendered free from any baneful character.

M. DOISY exhibited a funnel for facilitating the operation of filtering; it had a series of spiral canals running round it, thus preventing the filter paper from adhering too close to the sides, when the access of air is impossible.

M. J. H. C. HARRISON submitted a new form of drying box to be employed either for the desiccation of tissue or for drying plates destined for greasy ink printing.

M. STENFURT exhibited some samples of vegetable gelatine extracted from marine algae, which has been employed for some time at Rouen in the cotton trade. Pigments are easily employed to colour the material.

M. PELIGOT observed that it would be difficult, probably, to make use of this description of gelatine in photography where salts of silver come into play, by reason of the chlorides, bromides, and iodides which it is sure to contain.

M. PERROT DE CHAMEUX believed that it might be successfully employed with bichromate of potash, and stated that M. Leon Vidal had some years ago used a similar material in carbon printing, which was termed vegetable gelatine. In England experiments had also been made with a material of a like kind called agar-agar.

MM. BILLOT ET BILLAUDOT submitted some samples of pyroxyline prepared especially for M. Chardon's process. They also submitted a sample of a compound bromide, likewise in use by M. Chardon; it was composed of a mixture of the double bromide of ammonium and cadmium, and pure bromide of zinc.

A Member remarked, in reference to the solubility of pyroxyline, that it was well to apply the ether first, and then the alcohol. If alcohol was first added to the pyroxyline a gummy mass was the result, which took a long time to dissolve when the ether was added.

M. ANDRA offered some remarks relating to his experience of M. Chardon's process.

M. PERROT DE CHAMEUX also made some observations on the matter.

M. BRAUN submitted some carbon photographs, being reproductions from the Amsterdam Gallery.

M. DUCHESNE exhibited an instrument to register periods of exposure.

M. PRASZKOWSKI submitted a simplified heliostat specially constructed for micro-photographic work.

The proceedings then terminated.

Talk in the Studio

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The last meeting of this Society for the session will take place on Tuesday next, June 12th, at 5A, Pall Mall, East, when papers will be read on "Emulsions" by Mr. Herbert Berkeley, and on "The Continuing Action of Light on Pigment Printing" by Mr. J. R. Sawyer.

To Correspondents.

BUNGLE.—The toning bath turning brown and ceasing to tone is most likely the result of contact with some trace of hyposulphite of soda. Possibly your fingers have been in contact with the fixing bath, and have then been immersed in the toning solution. This will produce the effect you describe. There is no remedy for it; you can only recover the gold by precipitation.

AMATEUR.—Different pigments are used for stopping out pinholes, each manipulator, as a rule, having his favourite material. Something depends upon the portion of the negative: if the pinholes are in a dense portion, it is important to use an opaque pigment like Indian red or cadmium yellow; if in a thinner portion of the deposit, cobalt blue answers. Some use Indian ink throughout. 2. The acetate bath will produce a good purple black if properly used. If black, rather than purple, be desired, the lime bath is perhaps better. For the latter, the following is a good formula: chloride of gold two grains, chloride of lime three grains, water twelve ounces; to be used forty-eight hours after mixing.

K. C.—You will find Newman's "Harmonious Colouring Applied to Photographs" answer every purpose.

NEMO.—The best opal prints are most easily produced by the collodio-chloride process. The opal glass is coated with collodio-chloride of silver, and printed in the usual manner. It is difficult to produce prints in the camera, by development, so rich in tone and clear and brilliant in general effect. To produce enlarged prints, camera printing is necessary. Good ordinary collodion, and bath in working order, full exposure, and quick development are necessary to produce the best results. A pyro developer containing two grains of pyrogallio acid and a drachm of acetic acid in an ounce of water will give good results.

F. H. H.—A saturated solution of protosulphate of iron, consisting of 6 ounces of the salt in 10 ounces of water, will contain 288 grains in each ounce. We quote from the best authority on solubilities. Individual experiments in such matters often differ, as there is difference in the solubility of different samples of similar salts, difference in water, and difference in temperature; and these facts are too generally overlooked. The precise strength of developers is fortunately not a point of vital interest in manipulating. 2. A thirty-five grain bath in good condition will work as well and rapidly as a stronger one. Different makers work their lenses, in order of their rapid action, differently. Dallmeyer's portrait lenses are distinguished as A, B, and C; the latter being the most rapid and best suited for babies. 3. Bicarbonate of potash differs from the simple carbonate in possessing an atom more carbonic acid. The bicarbonate is used in most delicate operations, as more care is used in its preparation. It is a white powder. The simple carbonate is in crystals, and is familiarly known as washing soda. Both are, of course, alkaline salts; but the latter is more so than the former.

J. L.—Break up your glue into small pieces, and cover with water. If the glue be really good, it will not dissolve at all or discolour the cold water in which it is placed to soak. Drain off the water, place in the glue kettle, and boil. The glue having soaked up all the water it could, will dissolve, and become liquid with heat, and in this state form a strong cement. Frequent boiling somewhat destroys its adhesive power, and also its setting power.

M. L. F.—You require a thicker solution of india-rubber. The fifteen-grain solution with a large residue which you describe is practically much weaker, probably not more than ten grains to the ounce. 2. The thin foggy image which you describe may be due to the condition of the bath, or of the collodion, or of the developer. Probably you are using a new and somewhat tain collodion. Add a little more pyroxyline to the collodion, and a few drops of tincture of iodine.

COPYRIGHT.—The copyright in a portrait taken for a customer does not rest in the photographer without an agreement to that effect. It does not vest in either the producer, or the person ordering, without an agreement in writing made at the time, stating to whom the copyright is to belong. The producer of any photograph ordered and paid for by another has no right to sell the prints without the consent of the person so ordering; but neither of them possesses a copyright without an agreement. The only case in which the copyright vests in the producer without an agreement is where he produces the photograph at his own charge and for his own purposes. The cost of registration is one shilling for the fee, and one penny for the "form" to be filled up. Personal attendance at the Registrar's Office is necessary. Our Publisher will superintend the proper entries, and pay the fee of a form properly filled up, if one shilling and three pence in stamps be sent to him. A separate entry and separate fee is necessary for every view of any object. One entry and one fee only protects the picture in one negative, and any other negative with the slightest variation requires separate entry and fee.

CONFUSED.—Your former letter was mislaid; but, as you will perceive, is answered above. Your difficulty with opal glass arises from a simple cause; you are using flashed glass, and must, of course, use the flashed side, or you will get the effect of a double image and want of sharpness. If the flashed side is rough, it is imperfect; you must get the polished kind. Pyro will give you a warmer, richer toned image than iron.

C. WARMAN.—The letter was addressed and posted.

EASTBOURNE.—There is no reason why you should not register your copyright in the crying child; but you had better give it a distinct title instead of borrowing from a painting.

W. MATTHEWS.—In our next.

Several Correspondents in our next.

The Photographic News, June 15, 1877.**PHOTOGRAPHY IN AND OUT OF THE STUDIO.****DALLAS' PHOTO-MECHANICAL PROCESS—A TRAVELLED LADY PHOTOGRAPHER—THE JABLOCHKOFF LIGHT.**

Dallas' Photo-Mechanical Process.—Mr. Duncan Dallas is again to the fore with an improvement in photo-mechanical printing. Most of our readers have seen the charming bijou productions in the form of a miniature *Pall Mall Gazette*, *Fun*, *Times*, &c., which were produced by the so-called Dallastype; and now one step more of progress seems to have been made, for under the title of Dallastint, Mr. Dallas has successfully elaborated a process which gives half-tones in the printing press. The examples we have seen of the Dallastint process promise well for its future. One specimen was especially good. It was a business card of some drapery, or, rather, millinery establishment, and the main feature was a reproduction of a lady's bonnet, apparently in the latest fashion. The bonnet could, of course, have been engraved, and the block printed with the type in the ordinary manner, but had this been the case the result would have been far less pleasing than that secured by the Dallastint. The latter presents us with sketch and type all printed with the same ink, but the sketch, as one can see at a glance, is a veritable photograph of a bonnet, the straw thereof, and the ribbon serving to trim it, being most perfectly reproduced, and standing out in relief with all the characteristics of a camera picture. If Mr. Dallas can perform work like this, there will be plenty for him to do, for the production of a half-tone photograph, along with type, in the printing press, has been a stumbling-block over which many photographers have fallen. Some photographs of cloth, which he has also printed in the press, further demonstrate the capabilities of the process, for here, although we suppose the results are simply intended as tailor's patterns, the delicate fibre and phases of the pattern are reproduced with exceeding fidelity. We do not suppose that Mr. Dallas would succeed so well where he has wooded landscapes or foliage to deal with; but in the applications he has made of his process—and these must be infinite, if one could only think of them—he has hitherto been very fortunate. For business purposes, and also for book illustrations, the Dallastint should find plenty of applications.

A Travelled Lady Photographer.—Mr. Thomas Brassey's voyage round the world in his yacht *Sunbeam* is probably the first occasion of a pleasure craft having been taken by its owner upon such an excursion. Mr. Brassey was accompanied by his family and by Mrs. Brassey, who, as many of our readers know, is an accomplished photographer. We may, indeed, hope to see an interesting collection of pictures which have been brought home from this extensive voyage, for, as we have already notified in this journal, the little vessel had a portion of her hold fitted up as a photographic laboratory. It was a happy idea of the owner to make such an arrangement, for a tour such as has just been accomplished is a thing to be attempted but once in a lifetime. The reminiscences, therefore, which the photographs taken at the various spots visited will call up hereafter will be exceedingly pleasant, and from the fact that they were secured by the travellers themselves, they will be valuable, no matter whether perfect or not. The *Sunbeam* crossed the Atlantic and passed south of America into the Pacific, and then made a direct cut to Japan across the whole breadth of the ocean, Mr. Brassey calling at any of the islands in the Pacific just as he fancied. From Japan the little yacht went to China, thence to Singapore, and finally came, by way of the Suez Canal, to England. If Mrs. Brassey has made good use of her camera during the chequered journey, the yacht should have brought home a fine collection of pictures from all parts of the world; and it is to be hoped that

she may be prevailed upon to permit the public a peep at the interesting series, either at the autumn exhibition of the Photographic Society, or at some other opportunity. We congratulate Mrs. Brassey upon being the first amateur photographer who has attempted such a grand tour.

The Jablochkoff Light.—The new electric light or candle to which we have already referred in these columns, and which has been termed, after its inventor, the Jablochkoff light, is being experimented with in this country. Last week an extensive trial was to have been made at the West India Docks, and arrangements were made for illuminating a warehouse and quay by its means, to prove that the loading and unloading of a vessel could be carried on under such circumstances as well as in daylight. Unfortunately, the engine provided for the purpose broke down after a few preliminary trials, and the grand event of the evening did not come off. Four "candles" were, however, lighted up in the tent as a preliminary experiment, and these showed how simple and feasible the invention is. If the reader will imagine a candle with two wicks—the same being separated not by tallow, but by China clay or kaolin, so well known to all photographers—he will have a very good idea in his mind of the Jablochkoff light, only the wicks are in this case rigid and made of graphite. The "candle" burns away like other candles, but in a different manner somewhat. Electricity passes to the wicks, which represents, indeed, two electric wires kept apart or insulated from one another by the kaolin. The electricity from the two poles or "wicks" becoming united at the top of the candle a vivid current is the result, which has the effect of fusing and rendering incandescent the kaolin between the wicks. The kaolin at the top of the candle then emits a brilliant yet soft light—one, indeed, which the human eye may look at when surrounded by an opal globe. In the ordinary electric lamp it will be remembered the light is not only excessively intense, but the illuminating point, being but a spark, is of the most minute dimensions. In the "candle," however, it is a heated mass that emits the light, and hence the source is larger, and at the same time less intense. As the kaolin gradually fuses, the graphite wicks burn away, and so the "candle" burns down until all the kaolin has gone. This takes, however, some time, and a "candle" will last for hours. The Jablochkoff light, we may hope, will furnish us with the solution of electric illumination, for it overcomes at once two great difficulties we have hitherto had to contend against: it gives us a means of keeping the light uniform, and above all constant; and, again, it gives us a means of softening the vivid intensity of the rays. It is now seventy years since Sir Humphrey Davy exhibited the first electric light in this country at the Royal Institution, and yet to-day we know little more of this valuable illuminating agent than we did then. One would have thought that by the way science has progressed during the past half century, we should by this time have adapted it to our every-day uses, and that at the present moment our streets, bridges, squares, tunnels, theatres, &c., would all be lighted up by electricity. Yet we still regard the electric lamp with wonder and admiration, and have still to become familiar with it. The applications that have been made of it, however useful they may have been, are regarded in the light of extraordinary events; and if we have adopted electricity permanently in some of our lighthouses, this has only recently been the case. True it is that we have done something, so far as the generation of electricity is concerned, and no longer have recourse to a battery of four thousand metal plates, like Davy on the occasion to which we have referred. We now get our electricity from magneto-electric machines, and the quantity produced is in proportion to the power of the steam-engine employed to grind the armatures of the magnets. The amount of electricity is, indeed, only governed by the size of the magneto-machine and the power employed to drive it. Let us hope that the Jablochkoff light, which seems so

simple and effective in its action, may furnish us with the solution to a problem on which scientific men have been engaged for nearly three-quarters of a century.

THE NITRATE OF SILVER BATH.

BY B. J. EDWARDS.*

I MAKE no apology for calling your attention this evening to the old well-worn subject of the nitrate of silver bath. From the first introduction of the collodion process the bath has been to photographers a subject of the deepest interest, and often of the greatest anxiety. A good working bath, and one that can always be depended upon, is a source of joy and satisfaction to the conscientious operator, while a bath that is always getting out of order is a constant source of trouble and annoyance.

Until the happy time arrives when the photographer shall be able to dispense altogether with the silver bath as an essential part of the collodion process—and looking at the rapid strides made by emulsion processes the time may come sooner than we now expect or hope—the question of how to keep the silver bath in perfect working order is one which demands and deserves the most careful consideration.

If we consider for a moment the nature of the reaction which takes place when a plate coated with iodized collodion is immersed in the silver solution, we shall at once understand why it is that a silver bath in constant use so often fails to give satisfactory results. With such plates immersed a change takes place both in the materials and proportions of which the bath is composed.

A bath of pure silver and pure water will give, perhaps, the most perfect results it is possible to obtain; and with such a bath all will go well up to a certain point, after which deterioration, more or less rapid, sets in, and the bath eventually becomes unfit for work. For this reason constant efforts have been made to discover some substance which could be added to the plain solution of silver, which would have the effect of keeping the same in working order, or restoring it when contaminated by the unavoidable introduction of foreign and injurious substances.

Many things widely differing in character have been proposed, and more or less successfully used, for the above purpose; among others, I may mention nitric acid—at one time the panacea for all the ills the bath is afflicted with. Cyanide of potassium was suggested by Mr. Tully ten years ago, and has been lately strongly recommended by others who have tried this method. Nitrate of iron has been recently suggested by Mr. A. L. Henderson, who has also used and strongly recommended nitrate of baryta as an addition to the bath: and, lastly, we are advised to try an addition of a little hyposulphite of soda.

I do not propose in this paper to discuss the relative merits of the various remedies I have just alluded to—and most of which, except the last, I have carefully tried—but will at once describe my method of making and treating the nitrate bath. I do not claim the plan of working as a startling novelty, but it is one which, in my hands, has done good service in my daily work in the studio for the last three years; and in the hands of others who have it in constant use it has never failed to give uniform and satisfactory results. The formula is as follows:—

Solution No. 1.

Nitrate of silver (in crystals) ...	1 ounce
Common water ...	80 ounces.

Dissolve the silver in a Winchester quart bottle containing the above quantity of water, and expose to the sun's rays or ordinary daylight for at least twelve hours: with some kinds of water it will be advisable to boil and filter before adding the silver. It is better to make several Winchesters of this solution, and expose to light until required for

use. The clear solution will be a sufficiently pure and neutral solution of silver, about five grains to the ounce: it should be allowed to settle perfectly before being decanted and filtered for use, and great care should be taken not to disturb the sediment when pouring the solution into the filter. This precaution is absolutely necessary, as otherwise it will be difficult to filter the solution perfectly bright and clear. The best way of filtering is to well wet a tuft of cotton wool by holding it for a few minutes under a tap, and press it gently into the neck of a large funnel of glass or porcelain. Filter papers should be avoided, as they are apt to contaminate the solution.

To make a new bath, dissolve two ounces of nitrate of silver in twenty-six ounces of the No. 1 solution; then add four drachms of the following:—

Solution No. 2.

Iodide of calcium ...	30 grains
Distilled water ...	5 ounces.

Shake the bath after adding the No. 2 solution, and let it stand for a few hours; then filter, and the bath will be ready for use.

Plates excited in the bath made as above will be very sensitive, and the negatives perfectly free from pinholes; the solution will keep in order for a long time, and as soon as the films begin to show signs of the slightest deterioration from stains or insensitiveness, the bath solution is to be treated in the following manner, when it will be found that it is at once restored to perfect working order, and will produce negatives equal in every respect, if not superior, to those made in the new bath. To rectify the bath, pour the solution into a large flat dish or tray, and allow it to evaporate to about two-thirds of the total quantity; now test the concentrated solution with the argometer, and make up to the original strength, of thirty-eight or forty grains to the ounce, by adding a sufficient quantity of the No. 1 solution; filter, and the bath will be ready for use. The above treatment may be repeated as often as necessary; it has never yet been known to fail to restore a bath, however hard worked, to perfect working order. The fresh silver in the No. 1 solution will be found sufficient to replace the silver used in exciting the plates, thus keeping the bath of about the same bulk.

With regard to the best way of evaporating the bath, it is only necessary in the summer time to pour the solution into a large porcelain dish or *papier mache* tray, and leave it freely exposed for a few days in a warm place, or, in dry hot weather, for a few hours only. This plan of evaporating is by far the better one; but in the winter in this damp climate it is often necessary to use an evaporating dish, which can be placed in an oven or over a lamp stove without danger of breaking. There is no advantage in boiling the bath unless albumenized plates have been used, when the solution must be boiled to get rid of the albumen dissolved in it.

It is recommended, for the convenience of working, that two baths be kept in use, so that while one is laid aside to be treated as above, the other will be ready for work.

In making a new bath, do not on any account adopt the usual plan of iodizing with iodide of potassium, and avoid the use of a collodion containing a potassium salt. In the course of the experiments above alluded to it was abundantly demonstrated that the use of potassium in the bath or collodion is a fruitful source of pinholes.

The negatives should be soft and full of detail, clear in the deepest shadows, and of a reddish-brown colour. A cold, grey negative, wanting in gradation, and with the film partially eaten away in thousands of minute spots, is the result of a bath not sufficiently iodized. The remedy, whether for a new bath, or one that has been rectified as above, is to add to each pint of bath a few drops of the No. 2 solution, and filter for use.

With regard to the exact way in which the adaptation of the iodide of calcium to the bath, and the consequent for-

* Read before the South London Photographic Society.

mation of nitrate of lime in the solution, affect the working quantities of the bath—and especially in preventing pinholes—I would like to leave that matter in the hands of some of our able chemists who may care to investigate the subject. I may, however, just suggest that, as it has been proved that sulphate of silver is a prolific source of pinholes, it is possible that the nitrate of calcium in the bath acts as a safeguard against the formation of sulphate of silver, by taking hold of any sulphuric acid with which it may come into contact, and forming the insoluble sulphate of lime, which would be precipitated. Be this as it may, it is a fact that I have restored an old bath, giving a fine crop of pinholes, by simply adding the solution of iodide of calcium in excess, and filtering.

I find that the bath is best when fully saturated with iodide; in fact, I do not think it possible, under any circumstances, to over-saturate a bath with iodide of silver.

In conclusion, I shall be happy to answer any question, or to give such further information as any member may require; and I trust that all who adopt the plan I have described will find, as I have done, that whatever other difficulties may arise in the practice of photography, there will be no further trouble with the nitrate of silver bath.

A FEW EXPERIENCES IN THE STUDIO.

BY PETER LOW.*

I DESIRE to say a few words to-night by way of encouragement to amateur photographers, with, perhaps, a few hints to aid those who are just beginning to try their 'prentice hand in that portion of our beautiful art which, as a matter of course, I consider the highest, as well as the most interesting. I refer to portrait photography. Is it from the difficulties that have to be overcome, or a wish to avoid that particular domain of the professional, that so few amateurs attempt great things in the way of portrait or subject studies? I really think more might be done in that direction than I have either seen or heard about. Why not try composition, or even simple subject pictures, and not always views? What a field to display artistic thought and talent, and what an amount of pleasure might be given to others by a quaint conceit or a happy thought conveyed to our minds by such means; and as in many cases amateurs could afford more time for such studies than the professional photographer, it would be a great help to give that portion of our art the attention and prominence it deserves. I speak for myself when I say I am sorry I cannot, from press of business, devote a little of my time on picture subjects produced by the camera, by way of a little help and encouragement to any amateurs who may think of trying to photograph the "human face divine." I do not think it would be a bad plan to run over the taking and finishing of a portrait negative; at the same time I confess it would come easier for me to give practical illustration, to be understood better than I can hope to be by the pen. I have always found that beginners, either in painting or photography, are apt to imagine that a great deal, if not all, depends on the amount and variety of compounds used; however, as they gain experience, they find out that the simple palette, both of colour and chemicals, is the best, and the production of good pictures in either branch of art depends, not so much on the materials used, as on the amount of talent and perseverance in the user. With these few remarks we shall go to work.

In the first place, prepare your plates by first rubbing them with nitric acid and water, wash well under the tap, and, while still wet, flow the plate over twice with albumen (white of an egg to twenty ounces of water, filtered), and add a few drops of carbolic acid. This I have used for many years, and, must say, I have not found it to injure the bath in the least; by using it you can be certain of a

clean plate, and the film will be held firmly on the glass. Make up the nitrate bath of the usual thirty-five grain solution; and I have found it from experience to produce the best results, and to be more depended on, if no fresh silver be added to the bath as it is used; but simply, when it shows signs of decay, to put it and a handful of salt into the silver washings of the prints, and make up a fresh one. You thereby save reputation and temper, and get that bloom on the negative which I found impossible to get in an old bath. The key-stone to all good pictures is the bath, and this may seem to cost more than adding silver from time to time; but I do not think you will find it so in the long run. Filter your bath as seldom as you possibly can.

Collodion.—A mixture of two good makers works the best when a few days old; make up a little at a time, so that you may get plenty of detail, softness, and quickness of working.

Lighting.—A great fault in amateurs is using too much light; you will be surprised how little you can work with, if it be well directed and under control. An eight feet roof and side is quite sufficient, cutting off nearly all front light by a curtain, and then gently relieve the shadow side by the reflector. The one I use consists of two screens four feet square on a stand so arranged that the light can be thrown up; however, any arrangement will do, provided you use it properly. A newspaper on a head-rest makes a very good reflector, not putting it so close to the sitter that the shadows are destroyed, or the disagreeable effect of a cross light is produced, but just enough to enable you to see into the shades of the finished picture, and light up dark and heavy shadows; give a good exposure, and do not mind for one moment the impossible short exposure spoken about in most cases. Expose for your half-tones, and let the lights and shades take care of themselves. A great number of otherwise good negatives are spoiled through under-exposure; an over-exposed negative can be improved, but little can be done to an under-exposed one.

Developer.—One that is useful for all classes of work is—

Sulphate of iron	1 ounce
Iron of ammonia	1 "
Spirits of wine	1 "
Glacial acetic acid	1 "
Water	8 ounces

Put as little on the plate as you can, and do not rock it about. Keep on till every bit of detail is well out. If you can possibly do without, do not intensify. I find it better, when required, to do so after fixing, using a very weak solution of pyro and acid, and a few drops of silver, just enough to turn the negative to a greenish hue; but as a rule I do not intensify at all. I wish to impress the importance of keeping your negatives delicate, as you are apt to destroy the half tones. Negatives thicken as they dry, especially if you use heat. Varnish with a good hard varnish, and rub a little powdered resin on the face, to give it a good surface to take the pencil; retouch carefully with a pretty hard pencil, softening without entirely removing all hard lines; put lights on softly, and in their proper place. It will prove you have done the retouching wisely and well if you can see the skin of the face on the finished photograph, and not white paper. I am afraid I am touching on a sore point with some of the members who do not advocate improving the negative, but for one that does not require modelling, there are at least a hundred that do. Do not hesitate to remove any blemish or defects you cannot see by the eye in the person photographed. Most portrait painters, I find, object to retouched work; but, at the same time, they know well that what are called the pearly tints of the face are lost in the photograph. The delicate blue or green tints that so beautifully soften the edge of every shadow or wrinkle are not produced in the best negatives, and all require softening more or less to supply that defect in our chemicals. To model as it should be done requires a good deal of practice,

* Read before the Edinburgh Photographic Society.

and, above all, to know when to stop. Use the pencil on the face of the negatives, softening the shadows with crimson-lake on the back of the negative. Put on with a hard brush in the form of a stipple. The bath for paper which I find gives the best results is a fifty-grain solution, to be kept up to that strength, using a large bottle of solution, which only requires filtration once or twice in the year. All that is required is to decant carefully, and not disturb the sediment.

The toning bath I can recommend as a splendid keeping one is as follows:—

Gold	15 grains
Chalk	1 tablespoonful
Saturated solution of soda	60 drops,

to a Winchester of hot water. When cool, it is ready for use.

With the above you can procure any tone required, providing your negatives possess good printing qualities.

On the table you will find a few groups taken at Holyrood last week. They are simply developed, slightly washed, and not fixed till the evening. Others taken the same day were not finished till the following morning. I merely mention this to show that negatives are not spoiled by being kept for some time, but rather think they improve.

COLLODIO-ALBUMEN AND OTHER DRY PROCESSES.

BY GEORGE W. HEWITT.*

THE collodion, after being applied to the plate, is allowed to set well—rather longer than is usual in working the wet process. As soon as immersed in the bath, the plate is kept moving in a lateral direction by means of the dipper for twenty seconds; it is then allowed to remain in the bath from four to six minutes, depending on the temperature; it is then removed and taken off the dipper by catching one corner of the plate with a small piece of filtering-paper held between the fingers, and placed in a dish of rain-water slightly acidulated with acetic acid; the dish is moved so as to cause the water to wash across the film for a few moments, and then left while another plate is placed in the bath. The first plate is then taken up as soon as the greasy lines disappear from its surface, and is rinsed under the tap once only (not washed). A small portion of the filtered preservative is then applied to the film from one end of the plate, and is allowed to traverse the plate, driving the water on the plate before it. It is then drained off, and a second application made of fresh preservative, which is worked into the film by inclining the plate, and causing the solution to move in wave lines across its surface for about a minute; it is then drained off, and washed under the tap for a minute. After this washing flow over, for a few seconds, water one ounce, glacial acetic acid fifteen drops; then wash well, and finally flow with water one ounce, and the alcoholic solution of gallic acid fifteen drops. Dry spontaneously, or by moderate heat.

This seems like a lengthy operation, but in reality it can all be accomplished while the second plate is sensitizing; and as that interval cannot be decreased in any bath-process, the time between may as well be occupied as not. I usually make a half dozen 4-4 plates in little over half an hour. One of the greatest drawbacks in all bath dry processes is the tendency to streaks in the direction of the dip; by the lateral motion of the plate in the bath this is obviated, provided the bath has not been too much used. A bath that will work satisfactorily for the wet process may be completely unfit for dry plate work, from the accumulation of alcohol and ether in it. A clean bath in this respect is very essential. In moving the plate in the bath, should the latter be somewhat old, care should be

taken that the upper edge of the plate does not leave the bath, but is kept submerged; the bath solution in this case collects in small globules on the surface of the film, and, if only momentary, causes unequal action at these places, forming in the developed negative corresponding spots of different density.

The plate, on being taken from the bath, should present a uniform density when viewed by transmitted light, free from streaks and wave-markings in the film. In this respect, a plate that would make an excellent wet plate would, when converted into a dry one, be anything but satisfactory.

Handle the plate as little as possible, and always with filtering-paper between the fingers. In the washing, at first stages do not allow the water to wash from the fingers on the plate. The second dose of the preservative may be used for the first of the next plate. Do not get the solution of gallic acid stronger than three grains to the ounce; beyond this it becomes saturated, and is apt to form in crystals on the plate, causing spots. When the plates are drying, do not open the box or closet until they are completely dry.

The plates, if made with the above collodion, or with Anthony's yellow-label, will not require backing. On this point I can refer to our respected president, who, in the course of his experience with this process, gave an exposure of twenty-eight minutes, with the second stop of a rapid-rectilinear lens, to a view on the Schuylkill River, in which the distance was about twelve miles, and in the foreground white tombstones. The line between the sky and the distant objects is sharply defined, and the detail in the tombstones perfect, without the slightest particle of solarization. This plate was not backed.

The above will also serve as an illustration of the latitude in exposure these plates will allow of. The keeping qualities before exposure I have tested to the extent of one year, and the result was satisfactory. After exposure I have not had occasion to keep them over six weeks; but in this time there did not seem to be any difference in the development. I have never lost a plate by the film shipping. As for freedom from markings and spots in the film, the accompanying negatives will, I think, be found comparatively free from defects of this kind.

As to the exposure, from three to five minutes will be found sufficient, with a stop of about F. 25 on fairly-lighted subjects; but, as I have mentioned before, these plates will allow of great latitude in this respect, and more time can be given without injury to the high lights.

Development.—Wet the plate under the tap, and flow with a plain solution of pyro. (three grains to the ounce of water; allow this to remain on about a minute; if during this time the sky and high lights appear, continue with it (in cold weather warming the solution) until it brings up nearly all the detail; then add two drops of a citrate of silver solution, ten grains of nitrate of silver, and twenty grains of citric acid to the ounce. Keep this on until all the image is out, then add from six to ten drops more of the citrate of silver, which will bring up the density required. On the other hand, if there is no indication of the image in the first treatment with the plain pyro, pour off and add to it eight drops of a twenty-four grain solution of bromide of potash, and six drops of a saturated solution of carb. ammonia, and flow on after mixing by stirring. This will, in most cases, bring up the image; if not, a few more drops of the carbonate solution may be added. When the detail in the shadows begin to appear, wash off this developer well, and proceed with the pyro and silver as above. Fix in a strong solution of hypo.

You will see from the foregoing that, after all, this is but a modification of the Fothergill process. The application of the gallic acid confers the keeping qualities to the plates, makes, I think, a cleaner negative, and one more easily developed than without it. If the plates are

* Continued from page 268.

to be used within a week or ten days, the gallic acid wash may be omitted, with a gain, in sensitiveness, of about fifty per cent. to the plates, and then becomes the Fothergill process.

In conclusion, I may say that albumen, as far as my experience goes, is the main prop and stay of successful dry-plate work, whether used alone, as in the Taupenot process, or as a preservative to a washed collodion film; and if fairly tried, it will demonstrate for itself a peculiar fitness for photographic use not found in any other substance.

A FEW WORDS UPON MICRO-PHOTOGRAPHY.

BY M. A. RUTOT.*

VERY few have till now occupied themselves with micro-photography, notwithstanding the magnificent results which microscopists have obtained, and the obvious utility of productions of this kind. This abstention is due either to ignorance of photographic manipulations, or to an exaggerated fear of the difficulties which present themselves. Nevertheless, the difficulties are far from being so insurmountable as is generally believed, and in proof thereof I present to the Society some micro-photographs of various kinds obtained in a very simple way by M. Hempel, member of the Belgian Photographic Association. I may remark, in the first place, that the examples are far from representing the best examples which M. Hempel has obtained; on the contrary, they are the first essays made by an amateur which I place before your eyes. With a little more experience of photographic operations much better clichés will be obtained, I have no doubt, than those which are now laid before you.

The manner of operating is as follows. In any department into which the morning sun enters M. Hempel places his microscope upon a table. The instrument he employs is simply a small one of Hartnack's construction, upright, and bereft of its eyepiece. Above the microscope is fitted vertically, by the aid of a support, an ordinary camera (quarter-plate) capable of taking pictures nine by twelve centimetres, furnished with a focussing glass. The camera is in connection with the microscope by means of a little cone of black cloth, fixed to the photographic apparatus by the metal rim (where the lens fits in) and to the microscope by means of a rubber washer.

The object is put under the microscope in its proper place upon the object stand, and the sun's rays are directed upon it in the usual way by a mirror. The operator looks upon the focussing screen of the camera, and then, by the aid of the screw of the microscope, the enlarged image is focussed. If the image appears too small, it may be enlarged by gradually elongating the body of the camera; or if too big, the reverse operation is performed.

Having determined the size of the image, a diaphragm of very small aperture (about a quarter of a millimetre) is placed under the object, and a slight turn of the screw then furnishes the requisite amount of sharpness; the object may then be said to be focussed. In micro-photography the focussing should be rigorously exact, and a strong magnifier must be employed to view the image upon the ground glass; and to be able to judge the better of the half-tones, the operator should surround his head with a black cloth, to keep away the light. The focus properly adjusted, the operation of photographing may be commenced.

Before going any further, I may here call attention to a grave difficulty which may possibly occur: it is possible that the image may be perfectly sharp upon the ground glass, and yet when the collodion film is substituted there is a lack of sharpness and detail. In this case the operator has to do with a lens in which the chemical focus does not

coincide with its optical focus. Nevertheless, the evil is not an irreparable one, and a series of experiments properly undertaken will soon show how much the screw of the microscope should be turned to yield a good result. I may, however, state that I am convinced that defective lenses of this kind are much less frequently met with than is supposed to be the case, and good achromatic lenses always give good images. At the same time, in the case of colourless objects, or such as are of a monotone, like the diatoms, polycystines, and a large number of other organisms, the employment of very achromatic lenses is not indispensable.

In support of what I have just advanced, I may mention that the microscope which M. Hempel makes use of was not chosen for any special purpose, and gives with each of its true lenses pictures which have not the least trace of chemical defect.

The image of the object having been focussed, the latter is covered with a small piece of black cardboard: the ground glass is removed, and there is substituted for it the dark slide with the prepared plate. The slide is withdrawn, and by stooping down it is easy to direct upon the diaphragm the little luminous circle formed by the concentration of solar rays by the mirror; then, without loss of time, the piece of cardboard is removed from the object for a short time, and again replaced without hesitation. This brief period suffices to impress an image upon the collodion film; the dark slide is drawn, and the plate carried into the dark room to be developed, washed, and intensified if necessary, and finally fixed. From this negative may now be printed an indefinite number of positive prints.

So far as concerns the disposition of the apparatus, I would remark that I do not recommend the vertical arrangement which M. Hempel is compelled to have recourse to because his microscope is a vertical one. It is better to work with an inclined microscope, which allows one to place the camera in a horizontal position, by which means all the operations are considerably facilitated, and the whole affair assumes a proper stability.

In regard to objects to be reproduced in the micro-camera, two points have to be considered: their thickness and colour. As in the case of looking at an object under the microscope, the difficulty is to focus an object in every part, for some portions are sharp, while others are blurred, from the fact that they are not all in the same plane. Nevertheless, the photographic process offers many resources, and it is possible to obtain very extensive enlargements even with very feeble lenses. To do this, the exposure in the camera should be lengthened, the object, whether opaque or transparent, being always well lighted.

So far as regards colour, it is well known that certain of them—such as yellow, red, and green—do not reproduce themselves in photography according to their intensity, and that the prints appear with much darker tones than the originals appear to the eye. In cases where the objects present non-photogenic tints, they should be very powerfully illuminated, but with a very small diaphragm, polarised light being employed with advantage. Many organic substances of brown and yellow colour may have their tints reversed, or their outline lighted upon a black ground, by using polarised light.

The photographic process employed in micro-photography should be a very rapid one, and for this reason wet plates are the best; but now that dry-collodion processes, and especially the so-called emulsion methods, have been so much improved in England, these should be particularly applicable to micro-photography. By employing such a process, the operator might prepare in advance a whole series of plates, and these he would have merely to slip into the microscope one after another in order to secure twenty, thirty, or as many even as fifty photographs of different subjects in one morning.

THE NEXT PHOTOGRAPHIC EXHIBITION.

PHOTOGRAPHERS who contemplate contributing to the next exhibition of the Photographic Society will be glad to know that the date and other preliminary arrangements have been decided, and that the date at which the exhibition will open will give time for the most satisfactory preparation of specimens. The errors of judgment which led to failure last year will, on this occasion, be avoided, and the contemplated plans will afford every facility for a highly successful exhibition, which we hope photographers generally will do their part in securing. The exhibition last year was opened in the first week in September, a time when, unfortunately, a great many people were out of town—thus necessarily limiting the number of visitors—and a time, as many of the usual contributors declared, inconveniently early for photographers to prepare and send in pictures. The exhibition will this year open a month later; opening on the evening of Tuesday, the ninth of October, and continuing open until the middle of the following month. The exhibition will open with a soiree; but the stumbling-block of last year, the enforcement of evening dress, will this year be avoided, and the adoption of morning dress invited.

There will be this year also another powerful incentive to extensive contribution of high class pictures. The Council have resolved again to try the experiment of offering medals for various forms of excellence, artistic and technical. The value of awards of honour, as stimulating effort and securing the highest excellence, has been pretty generally acknowledged, although the wisdom of such awards in relation to works of art has often been disputed. In an art-science like photography, however, we think the arguments against offering medals for the best results in works of art can scarcely be sustained. The best argument against the distribution of medals in connection with exhibitions of photographs is that based upon experience, which points out that much heart-burning and discontent generally follow upon the awards. The last award of medals by the Photographic Society of London was followed by a painful disruption in the Society, which was by many attributed largely to the action of disappointed competitors at the Exhibition. We do not think, however, the disruption was due to such cause, nor do we think there is reason to fear any such injurious results in conjunction with the coming competition. Details of the forms of merit for which medals will be offered will appear in due time; but we may state that almost every possible form of skill, technical and artistic, is offered an incentive to do its best in the list of medals to be offered by the Society. Between twenty and thirty medals will be distributed; they will all be of bronze, and of equal value, although the record attached to each will necessarily modify the degrees of honour

conferred. The competition will of course be open to all photographers, whether members of the Society or not, and the concours of foreign photographers will be greeted with especial satisfaction.

Referring to the possible, or rather the inevitable, disappointments felt by non-successful competitors, the Council have determined upon a modification in appointing the jury of award, which, if it fail to secure universal satisfaction, will, at least, we think, be beyond challenge. Instead of selecting the jury as heretofore from members of the Council, it will on this occasion have a mixed constitution. It will consist of seven gentlemen, two of whom have been selected from the Council, two from non-official members of the Society, two from the art world: a Royal Academician and a member of the Society of Water Colours being requested to act, and the President of the Society as *ex officio* chairman. A jury so composed can scarcely fail to arrive at an accurate judgment of merit, and there cannot be a doubt that they will give decisions untingered by any motive but their conviction of the merit of the contributions. We hope that photographers generally will contribute, and that the exhibition may prove the best which has ever been held.

PHOTOGRAPHY AT THE ROYAL OBSERVATORY.

THE annual report of the Astronomer-Royal, Sir G. B. Airy, to the Board of Visitors was presented on Saturday week, at the Royal Observatory, Greenwich. Even a casual reader, glancing over the summary of this report, cannot fail to be struck with the employment now made of photography in connection with the records made at the Observatory, for, both in connection with the sun and with the stars, as also in respect to barometrical results, the camera seems to be in daily and nightly requisition. The Astronomer-Royal began by alluding to the Transit of Venus observations, and many of his audience were, no doubt, anticipating that something would be said about the completion of the results with which the Greenwich Observatory authorities have been occupied so long. But beyond mentioning the fact that all instruments lent had now been returned or made good, Sir George Airy did not vouchsafe a word upon the subject.

A better proof of the increased interest shown in the matter of photo-astronomy could not be afforded than the circumstance of there being at the present moment four photo-heliographs at different stations under Government supervision; namely, at Greenwich, at Chatham, at South Kensington, and at the Cape. The instrument at South Kensington, the Astronomer-Royal informs us, is "accompanied with equatorial transit, altazimuth, clocks, micrometer, &c., with appropriate huts, and chymical rooms, forming a complete representation of a first-class establishment for observation." There is another photo-astronomical station at Kew, where daily pictures of the sun are taken, so that a very complete solar record should be forthcoming. A word, however, may be said on this point, we think. It has been recently proved by photo-astronomical observations taken in the Engadine, a station at 6,000 feet above the level of the sea, where the air is of the purest and clearest, that far better and more trustworthy images are secured than can be secured on the plains in the midst of vapours, or in the neighbourhood of smoky towns. M. Janssen, whose observatory at Meudon is much further from Paris than Greenwich or South Kensington are from the centre of the metropolis, has already complained that his photographs suffer from the proximity of the capital; and we may be quite sure that if a wood-burning city like Paris interferes with the clearness and detail of astronomical photographs, London, which is twice as big, and ten times as dirty, by reason of the coal that is burnt within its limits, must have a very marked prejudicial influence.

The Astronomer-Royal informs us that "photographs of the sun had been taken on 140 days, of which 239 have been preserved, the photographs showing a complete absence of spots on 57 days, and on 29 of these there were neither spots nor faculæ." And here we come to another point of importance, which proves how necessary it is that the aspect of the sun should be daily registered. M. Janssen remarked on a solar photograph taken on the 15th April last a distinct record of a sun spot, while the picture taken by him the day before—that is, on the 14th—betrayed no trace of any such phenomenon. The inference, therefore, is that sun-spots may appear very suddenly, and do not develop as most astronomers have hitherto appeared to think. Should this turn out to be the case from further observation it will, indeed, lead most likely to a modification of the accepted theory respecting them. Already M. Janssen's observations have been attacked, and one astronomer has publicly enlarged against M. Janssen's views, asserting that M. Janssen is altogether in the wrong in bringing forward such a theory, as being against all the evidence hitherto adduced. But M. Janssen, in reply, simply points to his photographs; he brings forward no theory, but a fact which, as he says, any one can verify by looking at the photographs for himself. A more important proof how necessary it is we should have daily record of the solar disk could not be forthcoming, and when carefully secured, it is perfectly useless to set up ordinary ocular observations against them.

Sir George Airy in his report further alludes to the measures taken at Greenwich to secure by photography a record of the magnetic pulsations of the earth, and also of the barometric readers. In reference to the latter he says:—"The computation of the photographic records of the barometers from 1854 to 1873 has so far advanced that it is asserted positively there is no trace of lunar tide in the atmosphere, but that there is a strongly-marked semi-diurnal tide, accompanied with a smaller diurnal tide." There seems to have been no effect made as yet at Greenwich to add to our meteorological knowledge by securing cloud photographs, as recently suggested by Dr. Piazz Smyth, the Astronomer-Royal for Scotland.

EXPERIMENTS WITH THE CHARDON DRY PROCESS.

BY M. ANDRÉ.*

ENCOURAGED by the remarkable results obtained by M. Chardon, I have recently resumed my study of emulsion processes, of which I made a trial two years ago with but little success. I always think that the mutual account of our labours is interesting one to another, and I therefore take the opportunity of communicating what I have recently done in the way of experiment. I have kept scrupulously to the formulæ given by M. Chardon, if I have not altogether taken the same proportions of pyroxyline. As to the manipulations, I have followed in his wake, only making modifications where experience has suggested the same to me.

My first experiment was made with collodion made with equal parts of resistant and pulverulent pyroxyline. The sensitisation was brought about with 3·10 grammes of nitrate of silver for every 100 of mixed collodion, and seemed to answer well; but I lost a portion of the silver salts in dissolving it. After thirty-six hours, an analysis of the washing water gave me no appreciable trace of silver in excess, nor of bromide. By a singular chance, I had arrived at almost mathematical precision. I nevertheless chloridised my emulsion, and precipitated it forthwith. Dried and redissolved with an addition of quinine, and poured upon glass plates, it yielded a film of considerable opacity, and of a matt appearance; as I foresaw, the result was but mediocre. I obtained but flat and finely granulated plates, and in-

capable of being intensified, at least by alkaline development alone. I have the honour of submitting to the Society two examples of this first essay, which, I will frankly admit, are bad. I attributed my non-success to the collodion containing too large a proportion of pulverulent cotton. I again set to work, augmenting by one-third the resistant pyroxyline, and diminishing in the same proportion that of the pulverulent gun-cotton. This time I sensitized with 3·15 grammes of nitrate of silver, and on analysis I had the satisfaction of discovering a slight excess of silver salt. I believe that 3·10 grammes, or even 3·05, are sufficient, but on condition that not an atom of silver is lost in the operation of dissolution. After having neutralized the excess of silver by chloride of cobalt collodion, and otherwise followed M. Chardon's directions, I covered my glass plates, the film presenting a very different appearance to that of my first essay.* The film was rather less opaque, not in the least granulated, even when seen through a magnifier, and of a brilliant character. The result appeared to me very satisfactory. I have the honour to submit a dozen clichés taken with this emulsion, and I may remark that the time of exposure was exceedingly short, namely, from three to ten seconds for portraits in the open air (a doublet lens), and from thirty to sixty seconds in the case of views. I estimated that this was scarcely double that required in the case of wet plates.

In a third essay which I made with the emulsion, I wanted to bring about the sensitisation of the bromised collodion in a different manner, in order both to prevent any loss of nitrate of silver, and to accelerate the operation. I dissolved the desired quantity of silver with a few drops of alcohol and water in a litre bottle, taking care to place the same so that the bottom of it stood in a receptacle of hot water. As soon as the solution of the silver had been completed, and before the liquid had perfectly cooled again (to 30° to 35° C.), I poured—only taking care not to lose any of it—the bromised collodion into the solution of silver. At first I thought that the emulsion had failed, but after a few hours it was complete. The clots which had formed at first soon redissolved, and the plates, which I then prepared with the product (which had undergone all the proper operations), appeared to me as good in every way as those secured in the manner previously described. I am far from saying that this method of operating is new, but it is an appreciable simplification.

Finally, a little while ago I came upon the idea of precipitating the emulsion, not with cold water, but by means of hot distilled water of a temperature sufficient to boil, during a few moments, the emulsion poured into it. This time the product, as I foresaw, was much more voluminous, and in some degree of a flocculent nature, a condition very favourable to its dissolution. At the same time I noticed a circumstance which at first I could hardly believe—namely, that the water of precipitation and the rinsing waters were much less charged than heretofore with the white powder, which is composed in great measure of bromide of silver. However this may be, the spongy mass, when dried and redissolved, gave me an excellent film of a very resistant and remarkable character. I can hardly say as yet whether this mode of precipitation is really preferable to the other, but I can assure my readers that it gives excellent results, and that in this way the emulsion is perfectly washed. For my own part, I find it simplifies the operation a good deal, it being thus performed in a few minutes; but care must be taken to operate at a good distance from any light or source of heat, since the quantity of ether vapour given off in the operation might otherwise cause explosion and damage. I took the precaution, when carrying out the operation, to do it at night and in the open air. I exhibit to the members a series of four negatives taken with emulsion prepared warm in this way.

I have only, in conclusion, to express the desire, which I

* Read before the French Photographic Society.

* For complete details of M. Chardon's process see p. 226.

know is felt by all the members, that all who experiment with M. Chardon's beautiful process will, as I have done, give some account of their work, so that we may become well acquainted not only with the conditions of success, but also those of failure. In making known experiences in this way, whatever their nature may be, we shall soon be able to introduce a bromide of silver emulsion into every-day use, and employ it with more certainty even than is the case with wet plates.

THE PHOTOGRAPHIC PRINTING PROCESSES, WITH PARTICULAR REFERENCE TO THE AUBEL PRINTING PROCESS

BY G. BAUMANN.

ALTHOUGH it was reserved for the last decade to bring the photographic printing processes to a rather high degree of perfection, the effort to make photography in this direction useful and profitable is almost as old as our young art itself. Many able men have undertaken the solution of this problem, and, as a consequence thereof, having produced more or less favourable results, I think it important enough to give a compilation of the different methods employed. Before I do this it will be necessary to classify them, those where a print can be made from the original plate forming one class, while those where this is not the case form a class of themselves. We have, therefore, two classes, one comprising the *direct* method, the other the *indirect* method.

To the direct method belong—

1. Fizeau's heliographic process. 2. The Aubel process.

To the indirect method pertain—

1. The different asphaltum processes. 2. Lichtdruck. 3 and 4. Relief print and Talbot's steel-print process. 5 and 6. Photo-lithography and photo-sincography. 7. The heliographic processes.

The indirect processes having been, so far, more generally used, we will begin with them:

1. *Asphaltum Processes*.—If a proper solution of asphaltum (i. e., asphaltum dissolved in oil of lavender, ether, or chloroform) is poured upon a metallic plate or stone in a dark place, and the surface, dried in the dark, is exposed to light under a negative, the parts touched by the light will become insoluble; if the particles remaining soluble are now removed with benzine or oil of lavender, the underlying surface will be exposed, and the possibility is offered to let acid operate upon the thus exposed parts of this surface. In this way an engraved plate is produced which is suitable for printing.

Nicéphore Niépce made his first experiments in this way to obtain a picture in the camera, but he seems to have had no success with it. At some later time he tried to make steel prints with it. His nephew, Niépce de St. Victor, however, was the first successful one to complete this method. The last named exposed an asphalted steel plate under a positive, dissolved the unchanged particles with benzine, and etched the remaining parts with acid.

Negré exposes to light a steel plate under a negative, gilds, in the galvano-plastic manner, those parts exposed by washing with benzine, cleans the asphaltum entirely from the plate, and etches it with acid, the parts not gilded only being touched. One of the heliographic methods (that of Baldus) is also partly based upon the properties of asphaltum, as we will see afterwards.

2. *Lichtdruck (Light Printing)*.—If a coating of glue soaked with chromate of potassium is exposed to light under a negative, amongst other properties obtained after treating the coating with warm water will be the one upon which lichtdruck is based—that is, to receive only and fasten upon the lighted parts, correspondingly with the lighting, more or less ink. If now the coating, impregnated with printing ink and covered with clean paper, is put through a proper press with a slight pressure, the ink—that is, the picture—is transferred completely upon the paper. This method comes from Albert in Muni-

was practised about the same time by Obernetter and Gemoser. Presuming that the details of this method are sufficiently known, I restrict myself to this brief notice.

3 and 4. *Relief Printing and Fox Talbot's Steel Printing Process*.—Chrome gelatine plays again the principal part in these processes, but this time another property of it being used—by light to become indissoluble in warm water. If, therefore, a lighted chrome gelatine coating be treated with hot water, those parts that have become insoluble by lighting remain, whereas the soluble, unlighted parts are dissolved, and the coating does not now appear smooth, but is more or less etched. This etched surface was used by Woodbury, the inventor of the relief or Woodbury print, as a mould, to make by means of a hydraulic press a copy in metal. A thin coating of warm pigment (a mixture of colouring matter and gelatine) is poured upon this metal plate, and a sheet of paper pressed upon it lightly. The ink adheres to the paper, stiffens at once, and the picture with all its half-tones is completed. With any other ink no half-tone can be obtained, because the gelatine ink has solely the property to look lighter in thin coatings than in heavy ones. The results obtained in this manner are quite excellent.

Fox Talbot exposes a steel plate covered with chrome gelatine under a positive, having dissolved the unlighted parts with warm water; etches the exposed parts of the steel plate with acid, chloride of iron, or chloride of platinum; and obtains in this manner a deeply-etched drawing of the same.

5 and 6. *Photo-lithography and Photo-zincography*.—Niépce had already tried to transfer the photograph on stone, and created, by means of the asphaltum process, a picture upon it, and etched the same into the stone. Poitevin coats a stone with chrome-gelatine, because the ink will then stick to the lighted parts. Others make, by the last method, first a picture upon paper, transferring the paper picture, which has been inked, afterwards upon stone, which, by this manipulation, will be adapted for printing.

To obtain a sincograph, a picture is pressed upon zinc in the last-named manner, and etched, first with very dilute acid, and afterwards several times with a stronger solution. To prevent the raised parts from being corroded by the action of acid, care is taken to put powdered resin on them, and then heating the plate just sufficiently to melt the resin. The resin will run over the edges, and protect the sides in such a way that the raised parts remain broader towards the lower side.

7. *The Heliographic Process*.—The object of heliography is to get a printable copper plate. If the plate has been obtained, by a precipitate of copper, from a copper solution in the galvano-plastic method, the plates may also be called galvanic. An etched copper plate is obtained in a simple manner by coating it in the dark with chrome gelatine, and exposing it to light under a positive or negative. After the picture has been developed with water, the parts not lighted will be etched by a solution of chloride of iron. A relief picture is obtained, if a positive is used for lighting, and an intaglio one by using a negative.

Pretsch and Poitevin spread upon a glass plate a mixture of chrome gelatine and iodide of silver, and expose the same under a positive. After developing with warm water an uneven surface (coating) remains, which is filled up with a solution of gutta-percha. When dry, it is removed carefully from the gelatine coating, and the gutta-percha mould, covered with graphite, serves now for the production of a galvano-plastic copper plate.

Baldus uses an asphaltum coating on copper, and exposes the same under a positive. After developing with oil of lavender, the plate remains for a few days under the light, to be exposed afterwards, in a trough with a solution of sulphate of copper, to the influence of a battery. A relief or intaglio picture is formed according to the plate hanging on the negative or positive pole; and while in the first case the copper is deposited wherever the plate is freed from asphal-

tum, in the other case the copper is eroded. Scamoni, whose heliographs belong to the best productions of this kind, prepares his plates in the following manner:—Of the negative to be reproduced he makes a positive silver picture on plate-glass, and strengthens it well with a silver and pyrogallie acid solution. The plate, washed with water containing some ammonia, is after this strengthened with bichloride of mercury, and afterwards with a chloride of gold solution. After this, he strengthens the plate with water containing iron and pyrogallie acid, and dries the same over a lamp. Through this strengthening process the coating has been rendered well in relief, and is in condition to have a good printable copper cliché made from it by the galvano-plastic process. For this purpose a thin varnish is flowed over it, on which, before it is entirely dry, a little powdered graphite is thrown, to give the coating the necessary preparation for the conductor. The plate is now placed into the galvanic bath, and left in until the copper precipitate has the necessary strength. If the copper plate is now carefully separated from the silver coating, nothing remains to be done but to clean and block the copper plate to use it for printing purposes.

Herewith the indirect methods are concluded, and only the direct methods left for discussion. One of them,

Fizeau's Heliography, has been of but little value, for the plates produced could stand only a few prints; but it is deserving notice, because the experiments which Fizeau and others made with it date back at least thirty years. The idea was to get a printable plate by treating a Daguerreotype with diluted acid.

More important than this method is the latest of all—

The Aubel Method.—If liquid or gaseous fluoric acid is left to act upon glass, the acid dissolves the surface of the glass plate to a considerable degree; but while the liquid acid leaves the surface even and transparent, the vapours make the affected parts matt. If liquid fluoric acid is put upon a common varnished silver negative (an unvarnished coating tears too easily), and is left to act upon the same for a few minutes, it will be found, after entirely washing off the silver coating and drying the plate, that the picture, although weak, is completely etched upon the plate. A relief picture has been produced with those parts protected by the silver not affected, or very little, while the unprotected parts have been etched considerably more. If the attempt is made to rub lithographic ink upon such a plate, which appears to be etched deep enough, it will be found that the ink does not stick. If you let fluoric acid set upon an unvarnished, clear negative, strengthened with silver and pyrogallie acid solution, it will be found that a picture has been formed just as before, only with the difference that the affected parts are matt. If, now, lithographic ink is rubbed upon such a matt etched picture, it will be found that the ink adheres, and that it is possible to print the same as on paper. Still those experiments are not always successful, for the reason that the collodion film is apt to tear before the picture is etched deep enough, a consequence of which is that the acid acts over the entire plate. To prevent this, Aubel precipitates, by the galvano-plastic process, a little more silver on a pretty strong negative fixed with cyanide of potassium. The coating becomes so consistent by this manipulation that it will stand the following operation of etching with fluoric acid gas. After the gas has taken effect sufficiently, the silver coating is washed off, and the plate dried and put upon a lithographic press for printing, where it is fastened upon a lithographic stone. The lithographic colour is put on with a ball, and is a very difficult manipulation, as is also the printing. For that reason the first good and satisfactory print is transferred upon metal or stone by the well-known process, and from these the prints are made.

The entire process is a very difficult one, and claims a great deal of attention, the plates being of no use if they are etched too much or not enough, and will take too much or too little ink. A cleanly-etched plate-glass negative

looks charming, but it is advisable, on account of the danger of fluoric acid, that only those should busy themselves with etching who are conversant with it.

As seen from the above process, the results obtained must correspond exactly to the negative, with reference to the position of the several lines, for which reason the process is adapted to the reproduction of line drawings, &c. Half-tones cannot be produced, which explains why Aubel prints appear so hard and dry in comparison to the reproduced original. It may be that by the use of gelatine ink better results will be obtained.

In conclusion, I will remark that of all cited methods for the reproduction of half-tones, two only are suitable, the Lichtdruck process and the Woodbury process; all others give no half-tones.—*Photographische Monats Blätter.*

Correspondence.

CURIOUS SPECTROSCOPIC DISCOVERY.

SIR,—Most persons have become acquainted with a simple and readily-constructed apparatus by means of which drawings, portraits, or plans may be very closely copied. It consists, in its most primitive form, merely of an upright sheet of glass supported transversely, or affixed in a groove upon a flat surface. When it is in use, the drawing which the student proposes to reproduce is placed upon the board lying immediately before him. Then looking from left to right, the eye rests upon the glass, in which is seen mirrored an exact image of the thing to be drawn—imprinted, apparently, upon the blank sheet, which lies at the student's right hand. By this means he is enabled to obtain an accurate tracing of the portrait or sketch. Now, it will be evident that when the apparatus is efficiently constructed, this duplicate copy of the drawing can be withdrawn for examination at any stage of the work, and may be afterwards carefully replaced and proceeded with. So, too, it will be equally evident, that in the instance of copying a *portrait*, the substitution of any other face than the original one would be attended by a falsification of the image and a consequent destruction of the true identity. At this point, then, the reader may be requested to surmise for himself the arrangements that have been devised for communicating to the image, as presented in the mirror, the utmost possible degree of vividness, and for efficaciously utilizing the apparatus as an agent of judicial identification.

These details consist, in the main, of certain accessories for directing a powerful concentration of light upon the portrait with the employment of a mirror-plate of superior quality and of an especial tint. Thus furnished, it is next necessary that two life-size photographs shall be so arranged under the light, and on the reverse sides of the mirror-screen, that the vividly-illuminated features of the one shall be perfectly imaged at the precise angle and point of sight where the other appears. All being satisfactory, an entire novelty awaits the investigator. For, in the event of the photographs being those of the *same person*, and the attitude corresponding, then, at the *precise moment when perfect unison is reached*, one single image starts suddenly in existence, with all of those statuesque effects hitherto deemed peculiar to the stereoscope, and with all the vivid realism of life itself! Let me add that the *exterior changes* produced by lapse of time do not interfere with these results, though the deepened shadows and the "crow's-feet" are duly brought into view. It will suffice to say that I have not here specified all the paraphernalia requisite to bring about these effects in their most brilliant form; but the general principle will be sufficiently obvious to the intelligent reader.

I conclude by observing that I have placed into this apparatus—which, for lack of any better term, I designate an "identiscope"—certain life-size photographs, being on the one hand those of "young Roger Tichborne," and on

the other those of the "Tichborne Claimant." Doubtless I shall be expected to state the result of a test so conclusive; but, though the reply may be given with the utmost certainty, it is a disclosure which I do not here deem it needful to insert on merely my own unsupported authority.

W. MATHEWS.

SALVAGE COLLODION.

SIR,—Another case of collodion has been picked up off this town on Tuesday last, the 5th instant. It consisted of twenty bottles of Mawson's collodion, with twenty bottles of iodiser to make up the pints. It was enclosed in a tin case soldered down securely. It has either been thrown overboard, or may have been part of the cargo of some vessel which has undoubtedly foundered off here, as a large quantity of wreck-timber and ship's stores have been washed ashore near here. The case of collodion which was picked up near here some time back was ascertained to have been made by Mawson and Co. for another firm, who shipped it in bond, but who refuse to redeem it now. No purchaser has been found for it, though any price over three shillings a bottle (which is the duty) would purchase it. In that case there were forty-three pints, without iodiser; in this one there are twenty pints, with iodiser.

It is somewhat singular that such unusual salvage should in both cases have come ashore at the same place.—I am, sir, yours truly,

J. WALTER.

Proceedings of Societies.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

THE last meeting of the present session of the Society was held in the Water-Colour Gallery, Pall Mall, on the evening of Tuesday, the 12th instant, Mr. J. GLAISHER, F.R.S., in the chair.

The minutes of a previous meeting were read and confirmed.

The CHAIRMAN said that the Exhibition of the Society would be opened in that room on the 9th of October next. The Council of the Society had resolved to offer medals for various forms of excellence. The jury of award would consist of seven gentlemen: three from the Council, two from the body of the Society, and two gentlemen especially connected with the art.

Mr. SAWYER then read a paper on the continuation of the action set up by light on sensitive carbon tissue after the print has been withdrawn from the light. Mr. Sawyer exhibited a number of prints from negatives which ordinarily required an exposure of six tints. These had received one tint, and then were withdrawn from light. Each print had been cut into two portions, one half being put away in the dark and as much as possible preserved from moisture and atmosphere; whilst the other half had been placed away in the dark without any protection from the atmosphere. All the prints had been kept a certain number of hours before development, and the action set up by light had gone on in all, but much more palpably in those merely kept in the dark, but not sealed up from the action of the atmosphere.

Captain ABNEY wished that the gentlemen of the French Photographic Society who were so incredulous of this continuing action of light on carbon tissue could see the examples exhibited. He himself found an exposure of one tint with fourteen hours before development yield a print as fully done as if it had received four tints and immediate development. He was experimenting with the continuing effect of the yellow ray, and, indeed, of all rays; his experiments being carried out with the actual rays of the spectrum, not merely light through coloured glass. He hoped shortly to have something on the results obtained to bring before the Society.

After a vote of thanks the Secretary read a paper from Mr. Berkeley on emulsions.

Captain ABNEY read a note on the same subject, and the discussion was adjourned until a future meeting.

Mr. THOMAS read a brief note on the late silver bath discussion. He then exhibited a new lens by Voightlander, and showed examples of its work. He said that he had made it a point at all times to avoid bringing before the Society matters connected with his own trade manufactures; but he had not a similar scruple in bringing under the attention of members this last work of the great German optician. The lens was based on calculations made by Dr. Sommer. It was perfectly aplanatic, working with full

aperture, the relation of which to focus was one to six. It resembled the rapid rectilinear, but was of shorter focus. The examples he showed were produced with a twenty seconds' exposure. The price was low, and no discount was allowed, instead of fixing a high price and taking off a discount.

Mr. STUART (of Ross & Co.), as being himself connected with optical manufactures, rose to protest against the Society being made a vehicle for trade advertisements, for which the journals furnished a proper place. Mr. Thomas had shown nothing and stated nothing of a scientific character. He brought forward a lens like that of Mr. Dallmeyer, or that of his (Mr. Stuart's) own firm, and made statements about it which they had no means of testing. The twenty seconds he mentioned of exposure in Vienna might probably turn out to be one hundred and twenty in London. Then the allusion to prices was utterly unbecoming, and he protested strongly against the introduction of trade matters into the Society.

The CHAIRMAN said that but for Mr. Thomas' allusion to the question of price, he should have stopped the remarks he (Mr. Stuart) was making at once. He must request that the matter should drop.

Mr. THOMAS said there was a good precedent for introducing such matters to a Society in connection with this lens in the French Society, who had, when it was brought before them, appointed a committee to report upon it.

The CHAIRMAN called attention to some specimens of emulsion work shown by Mr. England, and then said the meeting would be adjourned until October 9th, when the Exhibition would be opened.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

At the meeting held on the 7th inst. the President occupied the chair.

Mr. B. J. EDWARDS read a paper on the "Nitrate Bath" (see page 278).

Mr. BAKER said that he had purchased for two guineas from Mr. Edwards the improved method of treating a bath, but he had to confess total failure with it, even after trying almost every kind of collodion. He did not think that he obtained fifty negatives before the bath gave up and caused numerous pinholes. This continued, in spite of every care, until he added a quantity of nitrate of baryta to the bath, after which he had no more annoyance.

Mr. EDWARDS felt sure that Mr. Baker must have deviated from his instructions in some way or other, otherwise he would not have experienced trouble with his bath. He had now made public his process, as the time had passed during which he considered himself bound to keep it a secret.

Mr. YORK, upon being called on by the Chairman for his experience in negative baths, said that he had nothing to say beyond this, that he, at one time, had been very much annoyed by the behaviour of his bath; but since he had adopted the habit of adding to it nitrate of baryta it had given him no further trouble.

Mr. WARNERKE had been much interested in all that had been said at recent meetings of the Photographic Society of Great Britain respecting the cause of pinholes, but had heard nothing to warrant him in setting aside his own hypothesis that they were caused by fulminite of silver.

Mr. WILLIAM BROOKS had almost entirely laid aside the nitrate bath, as he preferred to use emulsions; but he had made his nitrate baths with plain water, and sunned them well before using.

Mr. E. W. FOXLER thought it a mistake to conclude that pinholes were produced only from one cause, because there were many. This evil had been more prevalent since the introduction of bromized collodion than when simply iodized collodion was used. He described his method of sunning a bath, and passing to the subject of surface markings on collodion negatives, attributed this defect to want of proper draining of the plate. He then showed in what manner, by means of a well bath, the plate might be drained for a protracted period without its surface becoming dried.

After some observations by Mr. Bridge,

Mr. FRANK HOWARD advocated the addition of a drop or two of water to a collodion which gave such markings.

A Member having introduced the subject of the filtering of baths, collodions, and emulsions,

Mr. WARNERKE spoke of the advantages of glass-wool as a filtering medium.

Mr. TAYLOR had used a fine sample of felt for this purpose with advantage.

Mr. BROOKS thought that tow would fulfil every requirement.

Mr. FRASSELL thought that while glass-wool would answer

quite well for collodion, it would be liable to be decomposed by aqueous solutions. He also considered that it was possible that a double salt of sulphate of silver might be formed in the collodion, to which pinholes and other defects might be attributable.

Mr. EDWARDS having made a few observations in reply, and having received the thanks of the meeting for his paper,

The CHAIRMAN then adjourned the meeting for the summer recess.

It was arranged that an out-door meeting of the Society be held at Hampton Court on August 1st, at which the members are requested to bring their friends.

EDINBURGH PHOTOGRAPHIC SOCIETY.

An ordinary meeting of this Society was held in 5, St. Andrew Square, on the evening of Wednesday, the 6th inst., the President, Mr. LESSELLS, in the chair, when the minutes of the previous meeting were read and approved, and Messrs. J. M. Laren, J. Ballantyne, Jun., S. Wellstood, W. Porteous, and J. Morton, were admitted ordinary members.

The SECRETARY read a paper by Mr. Low, on a "Few Experiences in the Studio" (see page 279), and handed round several fine prints as examples produced in the ordinary course of business.

Mr. NORMAN MACBETH quite agreed with Mr. Low in his statement regarding the quantity of light that should be admitted into the studio, and thought that as a general rule photographers used too much, or too much diffused. To this cause was due the fact that in many cases it was difficult, in examining a portrait, to discover the source of light. With diffused light the photographer could never produce pictorial effect, and as a rule the less that was employed, if properly concentrated and directed, the better would the results be. One difference between an ordinary photograph and a work of art lay in the absence, in the former, of this poetry of art and sentiment, neither of which could be attained unless by a properly concentrated and directed light. Mr. Low, he thought, was equally right in avoiding intensification of the negative as far as possible. Photographs in common with paintings, contained, or ought to contain, first, high lights; then half lights, which was the region of colour; then middle tint, which was the beginning of shadow; and shadow. The "pearly tint" is the region of colour, and wherever much intensification has been resorted to, that is lost, and with it much of the charm that the picture ought to possess.

Dr. THOMPSON thought the remarks about the use of only a small quantity of developing solution of much practical importance. No doubt considerable dexterity was required, in the use of only a little developer, to get the surface of the plate evenly and rapidly coated, and so prevent unequal development; but the results were well worth the practice necessary to enable the operator to do it properly. The resulting negatives were much finer, and there never was any necessity for after-intensification.

Mr. BASHFORD said that Mr. Low's experiences were very similar to his own. He thought the key to the highest class work would be found in casting aside all ideas regarding the doctoring of the bath. He did not believe that really high class work could be made with a doctored bath, and under that appellation he included filtering. Years of experience had convinced him that whenever the bath gave evidence of being out of order, it should be thrown down, and recourse had to a new one.

Mr. YERBURY could corroborate Mr. Low's observations regarding the advantage of keeping the plates for a considerable time between sensitizing and exposure; he generally had a few ready, and found that when kept in a box they wrought very well after a period of at least two hours, and developed quite free from stains or markings of any kind.

Mr. DOBBS, in moving a vote of thanks to Mr. Low, said that the author of the paper had been too modest in his title. Instead of a few experiences, the paper really consisted of the valuable experience of a most careful and successful operator of many years standing.

A number of the pictures taken at the late out-door meeting at Bothwell Castle were submitted for inspection by Messrs. Mathison, Orighton, Turnbull, &c., and elicited a good deal of discussion, and some of them much admiration. In reply to the President,

Mr. MATHISON said that, with one exception, all the plates exposed at Bothwell were by the collodio-bromide emulsion, and of nearly similar quality—that is, containing just a mere trace of free bromide, and with a preservative of simple bitter beer. To this latter fact might be due the fact that long exposures were required, or, at least, that long exposures seem to give the best results. In his own case he had given from thirty to forty minutes, and members had an oppor-

tunity, by the examination of some of the prints on the table, of seeing whether he had given too much. The development was conducted by first moistening the plate with water, then flooding with a saturated solution of carbonate of ammonia to which had been added a few drops of an alcoholic solution of pyrogallallic acid. By keeping the pyrogallallic acid well down, the image came up at first thin and delicate, and readily acquired density on the addition, from time to time, of a few more drops of the alcoholic solution. As a rule, the restraining action of a bromide was not required; but should the development appear to be proceeding too rapidly, he added a little, which kept it within bounds. As a guide to beginners in the development of those plates, he might say that on an average the process in his hands occupied about ten minutes.

Mr. BASHFORD, until quite recently, had given little attention to dry plate work; but he had got initiated into the mystery by Mr. Mathison, and could bear out his statements regarding the facility of working the kind of emulsion in question. He had been trying it for enlarging, and found it to possess several advantages over the process he had been in the habit of using. It was simpler, not liable to stains or markings, and developed quite as quickly as did a wet plate, while any required density could be readily obtained. His first experiments were made with emulsion kindly supplied by Mr. Mathison, and not liking to ask for what he was not allowed to pay, he had obtained a supply of a commercial article, but found it required a much shorter exposure than that which he had been using; in fact, it was too quick for his purpose; but a wash with bitter beer was found to make it slow enough.

Dr. THOMPSON said that in dry-plate work generally, and especially in emulsion work, each operator succeeded best with his own preparation, or with that with which he was best acquainted, as he knew how to prevent a fault, or where to find a remedy. It was to him a matter of surprise that professional photographers had not long ago adopted an emulsion process for this portrait work. There were many advantages that would arise from being able to prepare a supply of sensitized plates for the day, and he believed, from his own experience in another direction, that if a plate were coated with emulsion and placed in water, it would keep for any reasonable time, and be quite as sensitive as ordinary wet collodion. Those who tried to coat a plate with emulsion for the first time might find some difficulty in getting a smooth uniform film. With ordinary collodion the plate might, in pouring off, be raised to the perpendicular without injury; but in the case of an emulsion it should be tilted off the level only enough to cause the superfluous quantity to flow into the bottle.

Mr. PRINGLE said that until the Cadsow Forest trip he had little or no acquaintance with dry-plate work, but must confess to a liking for greater rapidity than could be got with the emulsion under discussion. He procured some uranium plates, and, according to instructions, exposed from thirty seconds to a minute. He did not very well know how to set about the development, but Dr. Nicol happened to call, and from information got from him, he succeeded perfectly at the first trial, and managed to get a number of really excellent negatives.

Dr. NICOL then read a report from the late Exhibition Committee to the Council, and the meeting was adjourned.

WEST RIDING OF YORKSHIRE PHOTOGRAPHIC SOCIETY.

ON Wednesday, the 6th of June, the members and friends of the above Society availed themselves of their first monthly excursion for the season, to visit the Ryburne Valley. Proceeding by waggone from the Sowerby Bridge station, the party were conveyed up the valley; many of the excursionists alighted at Slitheroe Bridge, and proceeded by the stream up the valley, the scenery of which is something grand. Those of the party who proceeded forward in the waggone to the "Derby Inn" were joined there by their friends, when ample justice was done to the excellent tea provided, especially so by those who had walked up by the stream. No more chance had they of going out after tea, for the rain came on during tea, and continued till arrival back to the station. The Society intend going to Milner Field, the seat of Titus Salt, Esq., Saltair, on July 4th.

PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

A MEETING of this Society was held on April 3rd, President H. J. NEWTON in the chair.

Mr. SIDNEY BROWN exhibited a number of beautiful coloured photographs, painted on glass. Many years ago he had painted what were called ivorytypes, which he had now improved on as here shown. The colouring is fully under control, and changes

can be quite readily made from time to time, should such be desired, during the process of finishing. They are oil pictures, painted on the surface, and the cement in which they are embedded is permanent.

The SECRETARY said that there could be no question about the beauty of these pictures; they were far preferable in appearance to the old ivorytypes. To make the latter, artistic skill is necessary, and as the old ivorytype pictures are now being revived, the improvement of Mr. Brown will be quite opportune. He had never seen any ivorytype pictures that would last ten years.

Mr. J. WOOD wished to be informed of the best method for keeping a wet plate from drying during long exposures. He could not keep them moist for more than twenty minutes.

Mr. BROWN suggested that by placing the plate perfectly level on a table with the face down it could be kept moist for a long time; he had kept the plates so for hours. Glycerine is also successfully used for this purpose, after coating the plate, flow with glycerine, then expose and wash the plate. The gelatine is to be diluted with fifty per cent. of water. Treated in this way he could keep a plate moist for a week or more, and the plate lose none of its sensitiveness.

The PRESIDENT remarked that the putting on of glycerine or a solution of glycerine and water removed a portion of the free nitrate, which was essential for the development of the pictures. If, however, a solution of glycerine and water, equal parts, in which from fifteen to twenty grains of free nitrate to the ounce had been dissolved, that objection would be overcome. The President also stated that the collodion film would remain moist a long time if the back of the glass were kept wet. This could be done by laying a piece of wet blotting-paper on the back.

Mr. G. W. PAON said that a very good way to keep plates moist is to place a cap of ice in the camera-box; it prevents the evaporation of the solution from the plate. He found the ice much better than a damp towel.

The SECRETARY thought that the President's method of using dry plates much to be preferred when the work is to be done some distance off. He had kept plates moist for four hours, but then he had the inside of the camera damp, and the plate-holder padded with eight or ten thicknesses of bibulous paper.

Dr. M. N. MILLER enquired what was regarded as the best organifier. He saw it recommended in a photographic journal that, after the plate had been coated with the emulsion, it should be immersed in water, until the greasy lines were washed out of it, and then it is to be transferred to the organifier, which consists of beer and honey. His method was to put the plate in a bath of flat dish, and wash off the greasy lines.

The PRESIDENT remarked that, with some emulsions, a plate will not be benefited by washing with water prior to being treated with the organifier. If there is free silver present he would wash it, although Mr. Carey Lea succeeded by putting it immediately in the organifier. He found nothing superior to the organifier he published a year or two ago, and that is syrup of squilla, nuxvomica, and laudanum.

Dr. D. D. PARMELEE said that at the present time there was considerable excitement in the public mind in regard to blue light. He was frequently spoken to on the subject. He believed it to be nothing more than a pleasant shade, and had no peculiar curative property. He would enquire if there was any advantage in having blue light or blue screens over an equal amount of white light.

The PRESIDENT stated that the question of the actinic force of blue light was an unsettled one. Photographers who have experimented with blue glass have so far failed to agree, some asserting that they obtain increased actinic action by its use, while others maintain the opposite opinion. Looking at the question from his standpoint, without having experimented, he should say that the actinism of the solar ray could not be increased by filtering out a portion of it—that the whole was more potent than a part; and unless it could be shown that there was actually a retarding property of action in some rays of the spectrum, it would be difficult to convince him that there was increased potency in blue when separated from the other components of the white ray. According to Mr. Gaffield's statement, coloured light, whether violet, blue, or indigo, was less potent in actinic force than white light.

The SECRETARY used blue glass to a large extent, and found that different shades of it had different qualities. A general fault with it is that the tint is too deep a blue, and often upon a green or orange tinted glass. He considered a pure white glass flashed with blue, pure blue, very desirable. The light is grateful to the eyes. He believed the actinic force of the pure blue ray fully equal to the white, and for photographic purposes it has the

advantage of making the sitter feel at ease. A subdued blue light produced by frosted glass was far less actinic; he had never seen a frosted glass that was as brilliant. If the colour could be put on very thinly, by a solution which would leave the shade perfect, it would be a great advance. A good blue light could be easily controlled. He had worked considerably with the microscope in artificial light, and found that by using tinted glass very minute tissues could be made out even better than in sunlight. He saw objects that it was impossible to discern without it.

Dr. PARMELEE remarked that ladies often told him that their faces became freckled after wearing blue veils.

Talk in the Studio.

A MOIST COLOUR-BOX.—We have received from Messrs. Lechertier, Barbe, and Co., a marvellous example of cheapness. It is a moist colour-box, containing ten colours, all of which are guaranteed to be pure pigments. They are in a japanned tin box, the lid of which serves as a palette, for which purpose, also, a space in the box is provided. Three good camel's-hair pencils accompany the box; the whole being sold for one shilling. So far as we can judge by a hasty trial, the colours are very good.

SUICIDE OF A PHOTOGRAPHER.—A travelling photographer named Chapman, living in Milton Square, Margate, committed suicide by taking prussic acid on Friday morning. Jealousy is said to have been the cause.

To Correspondents.

S. M.—There is no efficient mode of removing water from alcohol but distillation. If you distil from lime or carbonate of potash, the spirit will come over, and the water remain behind.

R. S.—Hot weather often brings on a tendency to fog; and the mode of avoiding this difficulty is to use all the precautions laid down against fog. Keep the dark room well ventilated and cool; surround your bath with ice, do not use the iron developer too strong, and use a full proportion of acid.

Z. X. Y.—You will find the advertisement on the fifth page of advertisements in our issue for April 27th. See also this week.

CALLOW.—Albumenizing paper is, we believe, a fairly remunerative business when conducted with skill and enterprise. 2. The chief things required are knowledge and experience. The principal material appliances are large dishes, fresh eggs, good plain paper, a room which can easily be maintained at a suitable temperature for rapid drying, as free from dust as possible, and long rods upon which to suspend the sheets. 3. There is no work published on the subject. Articles have been written from time to time, but various points of formula and mechanical details have been preserved as trade secrets.

J. C. HAYDN.—The preservation of pure whites in developed paper prints is often a point involving trouble. One of the chief causes of difficulty arises from the fact that photographers are so frequently oblivious of the fact that excited paper is very sensitive, and do not take the pains to preserve it from all contact with light which they do a collodion film. In preparing and exciting the paper, insufficient care is often taken to exclude light, and the paper is often subjected more or less to the artificial light used. The use of acid in the silver bath is often useful. We have found the use of a trace of common salt in the developer useful in preserving the whites, but have never worked the matter out to a precise formula, we simply added a pinch of salt to the developer. If it retarded the development too much, we used less; and if it did not restrain enough, we added more.

M. & M.—You will find full details of printing on woven fabrics in our YARN-BOOK for 1868. We can only briefly indicate the details here. The whites of two eggs are beaten up with eight ounces of water, to which half a drachm of chloride of ammonium is added. The surface of the fabric is treated with this. When dry, it is floated on a sixty-grain silver bath. The printing must be very deep. The toning and fixing are conducted in the usual manner adopted with paper.

B. C.—The use of iodide and bromide of cadmium in collodion tends to produce the glutinous quality of which you complain. It is well to use these salts in conjunction with an alkaline iodide, such as that of potassium. The salts of sodium answer well.

M. M.—Chloride of gold is quite susceptible of adulteration, but whether the practice is common or not we cannot say; we think not. It is not difficult for a photographer to prepare his own according to instructions we have often published.

ANXIOUS.—The exhibition of the Photographic Society will open on the 9th of October next. Details of contributions and of the medals will be published shortly.

JANUS.—Arrived too late. In our next. Several Correspondents in our next.

The Photographic News, June 22, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

THE STATUE OF NICEPHORE NIEPCE AT CHALONS-SUR-SAONE—THE CYANOTYPE COPYING PROCESS.

The Statue of Nicéphore Niepce at Chalons-sur-Saone.—It is gratifying to learn that our neighbours in France are about to take steps to commemorate in that country the commencement of photographic research. Whatever may be said upon the much disputed question of early photography, there can be no doubt that in France the name of Nicéphore Niepce should be honoured as having been the first to catch up a sun picture in the camera and fix it upon paper, even if the image was not a very substantial one. We shall never, perhaps, arrive at a very satisfactory solution of the question as to who discovered photography, for the simple reason that it was not the fruit of any one man's labours; and no doubt several nations are ready to put in a claim to the honour, if information on the point were invited or desired. There is, indeed, not a single grand discovery or invention which is not claimed for half a dozen different men. The electric telegraph and the steam engine, like America of old, have many claimants, while gunpowder is said to have been found out at least a score of times. An English schoolboy who propounded that Roger Bacon was the inventor of "villainous saltpetre" would be well laughed at in a German college, where the name of Schwarz is always connected with the discovery, while both would probably get their ears pulled by a Chinese demagogue if they went to the Flowery Land with such stories. So far as we are concerned, we think the history of photographic discovery and research is best represented, as well as this can be popularly done, by the device upon the frontispiece of the *Moniteur de la Photographie*, which our colleague M. Ernest Lacan so ably edits. Here are depicted three cameos placed together, upon which are seen heads of Niepce, Daguerre, Talbot. This trio goes very far to represent all that is practical in the early history of photography, and we doubt whether a more brief and precise statement of the matter could be made. Niepce, undoubtedly, produced pictures from nature in the camera, and was in all probability the first to do so. To Daguerre, again, must be awarded the credit of having been the first to make known a beautiful and eminently practical method of securing sun images upon an opaque basis; and, in the third place, to Fox Talbot we owe the process of negative-taking, or, in other words, of obtaining pictures upon a transparent ground which, by reason of their transparency, can be employed as cliché to produce further copies. The process of photography as it is practised at the present day is essentially the process of Fox Talbot, therefore, and this philosopher, living at the present day, must indeed be gratified to see the results of his handiwork spreading so far and wide. The French nation, as we have said, has taken a step which will secure them from reproach in times hereafter. It has been determined to erect a statue of the first French photographer, and the site chosen is an appropriate one, that of his birth-place at Chalons-sur-Saone. The citizens of Chalons have taken the initiative, and have determined to collect subscriptions, not only from their own country, but from abroad, and by way of commencement have headed the list with the sum of five thousand francs. According to our French Correspondent the movement is not commenced a moment too soon, for he tells us that in the churchyard where Niepce and his wife were buried there is not even a wooden cross to mark their resting place, while brambles and weeds run riot over their graves. No doubt there will be many in Great Britain ready to contribute their mite to the erection of a statue to Nicéphore Niepce, the old retired lieutenant, who had enough confidence in English enterprise and fair play to undertake a journey to this country fifty years

ago—a journey, be it remembered, to a man of his humble means, which required some courage, in those days, to begin. He must have been pretty confident of the value of his process and of its capacity, to have journeyed so far. None can blame him for keeping his invention so close. He had worked at the matter all his life, and consequently hesitated to divulge the secret which constituted his sole fortune. "The sun did it," was the only explanation he vouchsafed to Faraday, when he showed the great English philosopher the first photograph of Kew Church, in the year 1827; and "the sun did it" were the quaint words that flashed up in Faraday's memory twelve years afterwards, when a friend gave a Daguerreotype into his hand, and began to explain how it was done. Nicéphore Niepce was dead then, but the Frenchman's terse explanation and his singular picture were so vivid in Faraday's mind that they served to help the Niepce family in securing their well-earned pension from the French Government. Faraday told Bauer, the Secretary of the Royal Society, the circumstances of the case, and these being properly represented to the French *Académie*, were instrumental in obtaining for Niepce's son Isidore the pension which the father himself would otherwise have enjoyed. And now we are told the Chalons citizens are bestirring themselves to do something to retrieve the honour of their fathers, and their own. Daguerre made a name, and acquired property; we in this country are never likely to forget Fox-Talbot, nor the eminent services he has rendered his country; Nicéphore Niepce, on the other hand, the humble philosopher and citizen of a small provincial town, was slipping fast from our memories when M. Victor Fouque came to the rescue and told the homely story of Niepce's life in that interesting work, *La vérité sur l'invention de la photographie*. To him photographers owe a great deal, and if the project of the Chalons citizens is crowned with success—as there is, indeed, every prospect—it will be more to the instrumentality of M. Fouque's pen, than anything else, that the statue of Nicéphore Niepce will be reared at his birth-place.

The Cyanotype Copying Process.—It is not unusual, as every photographer knows, for a process to remain *perdu* for some years, and then to get made known again with some mystery and circumstance. We see old friends revived in this way from time to time, and like somebody whom we may meet for the first time in a quaintly shaped hat or a different coloured coat than usual, we fail to recognize him at the first moment of our rencontre. But it is only for an instant that the deception holds good, and the well-known features are as apparent as ever as soon as we get on close terms again. The Cyanotype process, as Sir John Herschel used to call it, is the latest attempt at "fraudulent enlistment," and the circumstance that we have here to do with a genuine article, and not a spurious one, does not make the deception the less barefaced. The Cyanotype process as practised by Sir John Herschel is a very simple affair, and one that is found extremely useful for copying outline sketches, or multiplying tracings instead of using tracing-paper. Sir J. Herschel employed it, as does Professor Herschel, of Newcastle, to the present day, for making copies of their calculations or astronomical tables, the characters or figures being produced in white upon a blue ground. The paper, ready prepared for use by draughtsmen, or others, is to be purchased in Paris, and also, we believe, in this country, of Messrs. Marion, of Soho Square; but those who desire to make it for themselves can easily do so. Good smooth paper is treated with—

Citrate of iron (or ammonio-citrate)... 140 grains
Red prussiate of potash ... 120 "

Dissolved together in two fluid ounces of water. The solution can be kept in a glass stoppered bottle well wrapped up in a dark cloth, or shut up in a dark cupboard, for any length of time. It is applied by means of a brush or tuft of cotton wool, and the surface dried in the

dark. The paper is exposed to light under a tracing, being kept flat by glass plates, and the print fixed by washing in clean water for a few minutes. The ink lines of the tracing must be of an opaque black, such as Indian ink, &c., to prevent the rays of light from passing, and as a matter of course the copy will not be sharp unless the paper is kept firmly in contact with the tracing.

THE ACTION OF LIGHT, TEMPERATURE, AND ATMOSPHERE UPON PIGMENTED SENSITIVE TISSUES.

BY J. R. SAWYER.*

THE subject that I have the pleasure of bringing before you is not by any means a new one, and has, I believe, been introduced to your notice previously, more especially by our friend Captain Abney, who read a paper on this subject in the early part of 1872.

In the *British Journal Almanack*, 1872, I also find a paper by J. R. Johnson, from which I give an extract.

It was reserved to Lieutenant Abney to recognize the full value of this fact (viz., the continuing action of light on a partially exposed print), and to derive from it most important consequences in actual practice—so important, indeed, that they may lead to a complete revolution in the art of solar printing in carbon.

"Lieutenant Abney, having found that the action set up in the different gradations of a photographic negative was continued in darkness in the same ratio, each gradation or graduated tone of the picture continuing to increase in intensity *pari passu* with the others, determined, during the dark days of December, to give his prints one-fourth of the actual exposure which experience had found necessary for complete action, and to leave them to mature that action in darkness. Experiment showed him that fourteen hours' darkness were necessary to complete the action set up, and after that time had been allowed to elapse, the prints in development were found fully exposed."

I also believe the subject has been treated of more recently by our Honorary Secretary, Mr. Baden Pritchard; but at a time when the production of photographs in permanent pigments has become one of the recognized commercial elements in the business of the professional photographer, and taking into consideration the interesting character of the results, I venture to bring the subject before you this evening, with a view to afford some data for further systematic experiment.

Pigmented tissues are of two kinds as regards the methods employed of making them sensitive to the action of light. First, those made sensitive by the introduction of the sensitizing compound into the mixture of gelatine and pigment used in coating the paper; secondly, those made sensitive at any time after their manufacture, by being immersed in the sensitizing fluid; but as the action of which I propose to treat seems to be the same in both cases, I shall make no distinction between them, but simply speak of them as sensitized tissue. In making the material, consisting of gelatine and pigment spread upon paper which we call tissue, sensitive to the light's action, differing results are obtained by increasing or diminishing the quantity of the chemical salt employed as sensitizer; but whatever be the quantity employed, the beginning of a change is at once set up in the tissue itself, and the gelatine forming the medium for the colour has within it the germ of complete and absolute insolubility, even if preserved from the action of light and air in the most careful manner; but in the absence of light and air, the oxidation necessary to secure insolubility goes forward but very slowly; and the tissue may be kept many weeks in a sensitive and even usable condition.

But what I wished to call your attention more especially to this evening is, the change that gradually takes place

after the exposure of sensitive tissue for a very brief space to the action of the light. We will take for example (say) a negative which, with a given tissue, requires an exposure of six tints; if we take several pieces of this tissue, and expose them one after the other for a very brief period upon our negative,—say for one tint—we shall have a series of pictures which would be considered very much under-exposed; and if we develop one of these soon after its exposure to the light, we find, of course, that it is very much under-exposed, and, as a picture, worthless; we find that it is only in the very deepest shadows we get any vigour, that the half-tones will not hold, they wash away, and the whole is simply worthless.

Now let us cut our other pieces into two portions, distinguishing them by a letter on one portion, as well as the numbers. No. 1 we have developed, and we know exactly what effect is produced by the brief exposure to light; having cut the other portions in halves, let us distinguish them as Nos. 2, 2A, 3, 3A, and so on. Put those pieces distinguished by a number into a tin case, carefully sealed from the light, and as far as possible from the atmosphere; put those pieces distinguished by a number and a letter into (say) an ordinary drawer. We thus create separate conditions, one series being kept from the light and to a considerable extent from the atmosphere, the other being kept from light, but in contact with the air, and consequently to a great extent influenced by changes of temperature or hygrometric conditions.

To continue our experiment, let us day after day develop one of the exposed prints, of course developing together the halves that belong to each other, and the results will be eminently instructive. We shall find that, day by day, the action of the light will be continued—not a universal fogging and decomposition over the whole of the surface, but every gradation of light and shade preserving its proper balance, until at last a point is reached when the picture is as good as possible—that is to say, a photograph in pigmented tissue has been produced by allowing the light to act upon it for only one-sixth of the time supposed to be necessary, the remainder being due to the continuation of the light's action when the picture is no longer under its direct influence. But it must not be forgotten that our pieces of exposed tissues have been kept under slightly different conditions—both protected from the action of the light, but only one specially protected from the action of the external air. The one protected from the action of both light and air reaches its proper gradation of light and shade much more slowly than the one protected from the light only, showing that other elements than that of the action of the light enter into the making of the picture. The examples that I commend to your notice this evening have been produced in the manner I have described; the two halves of each picture have been joined together, and show in a marked manner the additional action conferred by the atmosphere not being perfectly excluded.

I have said that the moment the tissue is sensitized it contains the germs of its insolubility, and it must not be forgotten that insolubility means the power of producing photographs. It is a very frequent complaint that tissue washes up in development, that the half-tones become chalky and bare; but if the same tissue is kept for a short time it is no longer liable to these defects; it gradually acquires the necessary cohesion of its particles, and the resulting pictures are as perfect as possible.

Far from presenting difficulties, my decided opinion is, that in pigmented tissues we have means of modifications and adaptations perfectly unknown to photography before; not only have we colour—that is to say, the power of using almost any pigment that may be desired—but we have the power of combining pigments, of getting effects of force that are impossible in any other way. Take the case, for instance, of Turner's Liber; it is well known that the deepest portions of these are absolutely dug out of the plate with all the vigour of a master's hand; in the impressions—partly,

* Read before the Photographic Society of Great Britain.

no doubt from the skill of the printer, but mainly from the bold vigour of these lines and touches—they appear almost black upon the sepia ground of the picture. An ordinary photograph would be totally inadequate to represent these; it would make the picture all one tint; but a judicious method of combining colour in the tissue, giving a coat of a suitable dark colour, then upon that imposing a layer of picture colour, enables us to render these dark touches with a fidelity rivalling the best originals. The same principle holds good in many other cases. Given, for instance, a landscape: is it impossible, I will not say to produce natural colours, but to produce a harmonious and artistically tinted photograph simply by the super-position of colours over each other? To understand how this may be achieved is not difficult. A pigment picture is a picture in relief, the deepest shadows being represented by the greatest thickness of gelatine, the picture being produced under the negative by the light being enabled to penetrate the film according to the degree of gradation in the negative; suppose then we had a tissue formed of (say) four tints, the lower one a blackish-brown, the next a red, the next a yellow, the upper one a blue, in the deepest shadows the negative offering but little or no resistance to the light, would enable it to penetrate to the lowest coating; the next grade would go more or less to the red; the next to the yellow; whilst the sky, if a landscape, would be represented in blue; the white paper would represent those portions of the negative known as high lights, and would represent white clouds.

It is not my intention to enlarge upon this branch of the matter upon the present occasion, and I must equally decline to treat the question of obtaining a far greater and more exalted sensibility in tissue than we have at present; suffice it to say that even now it is possible to work tissue having a rapidity five or six times as great as that of ordinary silver paper, and this sensibility attained solely by the action of light and atmosphere upon tissue sensitized in the ordinary way. The points that I wished especially to call your attention to this evening are the continuing effects of the decomposition or insolubility conferred upon the gelatine by the addition of a chromate salt, and to bring before you examples of the practical utilization of that action in very much reducing the time of exposition of the prints.

In addition, I desire to emphasize most strongly the fact that newly sensitized tissue is not in the best condition for use; that it frequently produces hard and chalky pictures; that it requires long exposure, and that by keeping for a few days, the time allowed for the action of the light may be much reduced, whilst the resultant pictures leave nothing to be desired; this latter part of the subject was very well put by the editor of the *British Journal* in his issue of April 27.

As the summer is, we hope, now coming very near to us, I may be pardoned making a few remarks upon the special precautions to be taken in hot weather. Last summer a wave of failure swept over carbon printers which engulfed all but a very few; this wave of failure was synchronous with a wave of warm temperature. We may expect, at least hope for, warm weather again, and the necessity for coolness, both in the operator and the operated upon, will be manifest.

Keep the tissue in a cool, and not too dry a place. Let the sensitizing bath be kept cool either with ice in it or ice round the dish; once out of the sensitizing bath, it is all right at ordinary temperatures.

After the exposition of the tissue under the negative comes the first transfer to the glass or other temporary support; it is indispensable that this water should not exceed fifty-six degrees of Fahrenheit at most; employ ice here, do not allow the tissue to be handled with hot hands, and let it be fingered as little as possible. Write up in big letters in your operating and developing room

"KEEP COOL."

and you will have no more difficulty in working carbon or pigment printing in summer than in winter, and it is quite certain that a supply of tissue of two or three days old will

yield the best pictures, with a comparatively short exposure.

I hope soon after our recess to bring before you the results of many experiments in directions that I have only just been able to indicate. I believe pigment printing to be quite in its childhood, but that it will grow to the full stature and strength of manhood by the fostering care and careful experiments of many workers.

NOTES ON THE THEORY AND PRACTICE OF EMULSION PROCESSES.

BY HERBERT B. BERKELEY.*

I HAVE been requested by your Council to introduce the subject of *emulsions* for your consideration this evening. Your Society comprises so many well-known experimentalists in this branch of photography, that I hope my notes may provoke some discussion among them; more than this I cannot well hope to do.

I wish, more especially, to direct your attention to the theory of emulsions generally. I will mention some of the rules which have been dictated by the experience of others, and the theories by which they are accompanied, introducing a few experiences and suggestions of my own; and will conclude with a few notes on what, I consider, constitutes a good emulsion, and the best method of working it.

As, doubtless, with most inexact sciences, the followers of photography include men holding opinions often entirely opposed to those of others; this is sometimes so remarkably the case, that one is led to wonder how such discrepancies can occur; and we can only conclude that, where such complicated agents are employed, and where conditions of working so easily effect the result, widely different opinions are likely to be the rule, rather than the exception.

It is by no means improbable that we have not yet formed silver bromide in contact with the most suitable organic substance for the obtaining of the most exalted sensitiveness. How few substances have been employed for the formation of emulsions—a method of working which admits of greater divergence in this respect than the bath processes! It is true, however, that a fairly long list of additions to the collodion emulsion have been recommended from time to time—many of them organic—generally with the object of increasing the vigour of the developed image; but there can be no doubt that certain organic substances are highly conductive to sensitiveness when present during the formation of the silver bromide. Those whose experience with emulsions extends to the formation of them will readily admit this to be the case; they will probably even go further: they will recognise the fact that it is not merely sufficient to form the silver bromide in the presence of a suitable organic substance, but that, also, the organic compound which this substance forms with the silver nitrate must be present in the finished emulsion—I refer especially to washed emulsion, otherwise there will be a loss of sensitiveness, accompanied by other troubles of a mechanical nature. It behoves us, therefore, to keep in mind this fact when making washed emulsion, and not to rest satisfied that all will go well if the silver bromide be merely formed under favourable circumstances.

The influence of the fineness of division of the particles of silver bromide has not, apparently, received much attention, although a fine film is generally preferred. I do not mean in contra-distinction to a coarse film, but to a film in which the particles of bromide are microscopically coarser than those in the finer film. There is no doubt that a film in which the bromide is so fine that it appears like a stain, giving a very transparent plate, will yield a negative of the highest density; coarseness of film conducing to the opposite result. It is my opinion that the fine films bear more forcing without fogging, but that they

* Read before the Photographic Society of Great Britain.

are not more sensitive than the coarser films. I rather incline to the belief that an extremely fine state of division is inimical to sensitiveness; that this is contrary to general opinion I am aware, but my experience leads me to this conclusion.

The influence of excess of silver nitrate on emulsions is generally admitted, but the theory of its action appears yet to be a matter for speculation. In the case of collodion emulsion it is commonly supposed to act upon the silver bromide and on an organic constituent of the collodion, the result being either a chemical combination of these latter, or a mechanical mixture. Practically we find an increase of sensitiveness and density to be the result of this method, though by long keeping the emulsion arrives at a stage where thinness of image and fog is the characteristic. The thinness is due, I believe, to the mechanical state of the collodion film, whereby development takes place on the silver bromide, unrestrained by the enveloping collodion film.

Excess of silver on gelatine emulsion does not seem to act in the same way as on collodion. We appear rather to obtain an increase of density, than an increase of sensitiveness, though there is generally some gain in this direction too. It is, however, a curious fact that a large excess of silver nitrate is prejudicial to sensitiveness, an experience which is borne out by the fact that keeping a gelatine emulsion with excess of silver brings about a loss of sensitiveness, and clearness rather than fog.

The subject appears to require further investigation to prove that silver bromide is acted on by silver nitrate, *per se*; though, doubtless, an organic compound of silver is formed which conduces materially to both sensitiveness and density; and in the case of collodion the film is modified mechanically so as to be more easily acted on by the developer.

In the case of gelatine the film is not affected mechanically; hence we fail to obtain much gain in sensitiveness. It is also possible that the organic reaction is not so favourable as with collodion.

If silver nitrate act on silver bromide when unrestrained by nitric acid, and more slowly when restrained, it is only natural to ask what the compound is which causes such a general darkening of the film on applying the developer. I am not aware of any theory connected with this "fogging action," and I suggest the formation of sub-bromide of silver. The presence of nitric acid restrains this action for a considerable time, varying with the circumstances of each particular case. But I am much inclined to dispute this theory, and to suppose that a change in the character of the collodion, either chemical, or physical, or both, is the cause of this abnormal action. We do not experience this action when forming an emulsion with either gum or gelatine, and though both may be "restrainers" in a sense, it is difficult to suppose that either would entirely prevent the formation of the sub-bromide.

Since writing the above, Captain Abney has told me how he believes the sub-bromide of silver is formed in the emulsion. He says that it is formed independently of the silver bromide, which results from the addition of the silver nitrate to a soluble bromide; but I leave it to Captain Abney to make his own remarks on his investigations, which I have no doubt he will do, if present here this evening.

(To be continued.)

ON THE ALBUMEN EMULSION.

BY CAPTAIN ABNEY, R.E., F.R.S.*

SINCE I understand that Mr. Berkeley has been referring in his paper to an emulsion process with which I am somewhat connected, I have ventured to offer a few remarks to the Society respecting it. Several friends who have tried

* Read before the Photographic Society of Great Britain.

it state that there is a tendency for the film to leave the plate, curling up when drying. Except when working with a thick emulsion in which ether was decidedly in excess, or when the pyroxyline was of a very contractile nature, I never found this difficulty arise. This, of course, may be overcome by using a more powdery cotton and less ether. I will briefly summarize the method of preparation. Sixteen grains of ordinary pyroxyline, such as employed in ordinary collodion for the wet process, are dissolved in six drachms of ether and six of alcohol. In this quantity of collodion are dissolved twenty grains of zinc bromide; one grain of dried albumen is added to this after being dissolved in one drachm of water, in which there may be a drop or two of ammonia (if necessary), to secure solution. The albumen solution must be added carefully, drop by drop, till an emulsion of albumen is formed. The collodion may now be neutralized by a little nitric acid, and enough silver nitrate dissolved in the ordinary manner to give an excess of at least four grains in the above quantity of collodion over and above that necessary to convert the zinc bromide and bromine and albumen into silver bromide and albuminate. A saturated solution of bromine in water is prepared in the dark, and ten drops added to the collodion after three-fourths of the silver solution has been stirred in. The remainder of the silver is then added. By adding this bromine water, nitric acid is liberated, silver bromate formed, and also sub-bromide of silver converted into bromide. This method of adding the bromine prevents the formation of any appreciable quantity of bromal, a product which is very detrimental to sensitiveness. The emulsion should stand eighteen hours, and be then washed and dried in the usual manner, leaving a very slight excess of silver in the pellicle. The pellicle is dissolved in equal parts of ether and alcohol, care being taken to add no more than is requisite, as in a thin emulsion it is difficult to secure intensity. The peculiarity of this emulsion is that a film of it transmits the green and violet rays, absorbing the red, to a certain extent. I exhibit a film which shows the peculiarity. This emulsion is very sensitive, chiefly, I suspect, on account of the fine state into which the particles of the sensitive salt are divided; the transmission of the blue, and absorption of the red, show the minuteness of the grain. The emulsion is sensitive to the red rays of the spectrum, and also to the less refrangible dark rays. At the time I was afraid that the heat of summer might alter the plates, owing to the dark radiation, but these are apparently so low in the scale that they are ineffectual to cause decomposition. It may seem a stretch of imagination, but the day may not be distant when, in a darkened room, it may be possible to photograph a black hot poker, or a kettle containing boiling water.

REMARKS ON THE SILVER NITRATE BATH.

BY R. W. THOMAS.*

I REGRET that I was prevented by circumstances from being present at the last meeting of the Society.

The discussion that has taken place for several consecutive evenings on the Silver Nitrate Bath has been, and must obviously be, most incomplete as long as this subject is isolated from, and is made to form no part with, the composition of the collodion, which, sooner or later, effects the changes that are a source of trouble to photographers.

For very obvious reasons the subject is not likely to be properly ventilated. As one of the largest manufacturers of collodion in this country, I must protest against the assumption that a sulphate is likely to be introduced by either want of care in washing the pyroxyline, or by its introduction through impurity in the iodizing salts employed.

I have always maintained, and a very large experience confirms my view, that in order to obtain the most satis-

factory results, absolute purity, both in the preparation of the silver nitrate and the water used, is a most essential condition.

As a chemist and practical photographer, I set my face entirely against the pump water and sunning processes, and will further add that re-crystallizing silver nitrate does not altogether free it from deleterious impurities, and that distilled water fit for making a bath is not so easily obtained as some may think.

The preparation of silver nitrate bath has been for some years a success with me, commercially speaking; many of our largest photographers avail themselves of the convenience I am able to offer by keeping ready prepared, and sending out in a perfect state, an article of so much importance.

I have always been careful not to speak at these meetings on subjects bearing on trade manufactures, but on this occasion I have been called out, so to speak, and silence on the subject might be improperly construed.

I have always maintained that neutrality in a silver bath (I do not mean of course alkalinity), quite a possible condition when the water is saturated with oxide of silver, is the proper condition for this solution, and should this state be found unsatisfactory in working, the fault lies either in the light used in the operating room, or in the want of a slight trace of iodine in the collodion. My paper on this subject is tolerably well known, and will be found in my treatise on photography.

EPITOME OF THE MANIPULATIONS AND DEFECTS INHERENT TO HUSNIK'S LICHTDRUCK.*

The Manipulations Summarised.—1. The patent glass plates are rubbed with ammonia, and then cleaned with spirit and levigated chalk.

2. Plates previously employed are put into a caustic lye (soda or potash) solution.

3. Matt plates are invariably grained with the finest emery.

4. The plates are finally washed, rinsed in clean water, and dried.

First Preparation.—1. White of egg is beaten to a froth. 2. The white of egg, when settled, is mixed with soluble silicate and water. 3. The solution is filtered. 4. The plates are dusted. 5. The plates are breathed upon, and the albumen and silicate solution applied. 6. The plates are set up to dry. 7. The superfluous liquid which has been poured off is filtered. 8. The operations 5, 6, and 7 are repeated until all the plates are coated. 9. The plates are warmed at 30° to 35° Reaumur, or allowed to remain a day. 10. The plates are washed for some time in cold water. 11. They are set up to dry.

Second Preparation.—1. Preparation of the gelatine solution. 2. The drying box is warmed to 45° Reaumur. 3. The plates are put in to warm. 4. The plates are dusted. 5. The gelatine solution is spread upon the plates. 6. The superfluous solution is poured off. 7. The drying box is opened and the plates put in, together with the remaining solution, in a stoppered bottle. 8. The box is closed. 9. The box is maintained at a temperature of 45° R., for drying the plates. 10. The solution drained from the plates is filtered. 11. The solution is spread upon the dry warm plates a second time. 12. The superfluous solution is allowed to fall off in the opposite direction to what was formerly the case. 13. The plates are put into the box to dry, being placed in a reverse position to formerly. 14. The plates are dried a second time, at a temperature of 45° R. 15. The plates are taken out of the drying box and put away. 16. The films are printed. 17. They are put into cold water to wash. 18. They are dried. 19. The plates are moistened. 20. The printing

surface is wiped. 21. The plate is inked up with litho varnish. 22. The paper is applied, and a proof pulled.

Defects and their Cause.—1. If the glass plates get scratched in polishing, it is due to the emery not being moist in every part, or to too much pressure being used in commencing the operation, or the emery has not been properly levigated.

2. The solution first employed sometimes has bubbles when filtered; the cause of this is, that it is allowed to fall; the liquid should always be permitted to run down a glass rod.

3. When setting up the plates to dry, dust from the floor settles upon the film and dries. To obviate this, the floor should be covered with filter paper.

4. The gelatine will not dissolve at times in the bath. It should be soaked well in cold water first, and then dissolved before the bichromate is added.

5. The waste solution from the plates runs down the sides of the box, and collecting at the bottom burns and emits noxious gases. This is prevented by putting linen frames into the bottom of the box, with sheets of filter paper, and changing these frequently.

6. The surface of the gelatined plates is matt in places when taken out of the drying box. The cause of this is the imperfect closing of the cover, or an accidental opening, or a variable temperature during drying.

7. If the plate has at one end a different grain to the other, the temperature has not been raised quickly enough to 45° R., or it had cooled too much when opened.

8. When the grain is too coarse and the film too stout, the reason is, that too much spirits has evaporated, or the plate has dried in too upright a position. A coarse roller produces the same defect.

9. When the plates have a brownish colour, and the images develop badly on exposure, there has been too much heat in drying, or an unequal distribution of the warmth.

10. Sometimes the plate, even when manipulated with a thick ink, gives no half-tones in the shadows, and gives monotonous flat pictures; the cause of this is over-exposure, or the plate has been under the hands of the printer too long.

11. When the plate gives white impressions, which show no half-tones in lights, it is a sign of too short an exposure, too little glycerine in the damping water, or that the plate has been dried at a low temperature.

12. If, after five or ten good impressions, there follow pictures flat in the shadows, the reason is that there is not grain enough, and that the plate has been dried at too low a temperature.

13. If the prints are on one side darker than the other, then the film is of unequal thickness.

14. When the glass plate breaks in the press, it is a sign that the bed is unequal.

15. In case the paper sticks to the high lights, and tears off, it is a proof that too soft a gelatine has been employed, or that the work-room is too warm. The defect may also be due to the paper not being sufficiently moistened, or to there being insufficient glycerine in the damping water, or to the circumstance of the latter not being cold enough.

16. If spots upon the print or double impressions result, the reason is, that the paper has been laid over the whole surface of the plate, or that the bridge has not been used; or it may be that the paper was too dry.

PLATINUM PLATING.—M. Dodé has patented a plan for giving cast objects a coating of platinum. The object as cast, or after being enamelled, is first washed over with a brush dipped in turpentine; a mixture of borate of lead and oxide of copper is next applied, and the casting dried in a drying stove. The next step is to immerse the object so prepared in a composition of borate of lead, German litharge, platinum in the state of chloride, ordinary ether, essence of lavender, and aniline (f) acid. Finally, the platinized object is submitted to the action of heat.—*Scientific American.*

VENTILATION OF GRIEVANCES.

We publish a letter on another page in which Captain Turton calls attention to what he conceives to be a want in photographic journalism. Similar suggestions not unfrequently reach us. Captain Turton thinks there is need for a freer and more outspoken opinion in the journals as to the demerits of various articles commercially supplied to photographers: commercial dry plates being the sinners most needing denunciation at present.

We can well understand the position taken by Captain Turton, and others who think similarly. They argue that as certain goods are brought under the attention of photographers in the journals, their manufacturers being allowed to parade the virtues of their goods in the announcements, it is surely legitimate when they turn out imperfect that the journals should be open to complaints whereby others might be warned against purchasing inferior articles. And they often argue further that as the Editor of a journal is regarded as the "guide, philosopher, and friend" of struggling photographers, and is set in a watch-tower, that his voice should be heard in denunciation of sham pretensions amongst advertisers. A little reflection will show that both these assumptions are erroneous, and that an Editor should not himself, or permit others, lightly, to denounce the commercial products of any manufacturer. In the first place, the law of libel steps in to protect any one from the publication of statements which may injure him in his business or professional avocations, and that without reference to the truth or falsehood of the libellous statements. As the proprietor of a journal is the sufferer in the case of libel, an Editor is bound to maintain a scrupulous supervision as to the publication of anything which may by possibility come under the operation of this law, the comprehensive powers of which are by no means well defined. If no such law existed it would only be just that the same care should be used. It is a somewhat serious matter that the commercial reputation of any should be perilled upon the opinion of an individual who, although honest, may not be infallibly capable. We have frequently seen cases in which subtleties of manipulation almost, or quite, impossible to trace or detect, have made all the difference between success and failure. We remember a special case in which a packet of commercial dry plates were under test. One had been exposed and developed by a skilful operator, the result being dense fog. Another plate followed with a similar fate. In the dark room was a photographer of pre-eminent skill, but quite unfamiliar with the plates in question. He tried a plate next. The varied solutions used in alkaline development had all been prepared previously by Operator No. 1. Operator No. 2 had simply mix sufficient in his developing cup. He proceeded to develop, and produced a brilliant, excellent negative; otherwise the plates would have been denounced as useless. It does not follow that all failures are due to any failure in the photographer's skill; but even then it is not legitimate to publish denunciations to the detriment of the manufacturer. *Caveat emptor*, is an old and a wholesome motto in commerce. Absolute certainty, or guarantee of the excellence, of the goods of any firm can rarely be had, except in cases where the long established reputation of a firm has established its position beyond doubt; and a reputation so acquired is valuable trade capital. With experimental manufactures there is generally some risk, which must be undergone by both manufacturer and purchaser, and it is certainly not the duty of a conscientious journalist to denounce or permit others to denounce occasional imperfections in goods, whether advertised in his pages or not.

But whilst a published journal cannot, with propriety, enter into the discussion of such point, and no photographic society permits the discussion of commercial questions, we think we can point out to Captain Turton and to others in his position, practising photography with comparatively little sympathetic intercourse with other photographic workers with whom they might discuss such grievances. We claim some credit for self-sacrifice, inasmuch as the remedy we are about to suggest may, in some respects, be slightly antagonistic to the interests of regular journalism. We suggest the establishment among groups of amateur of "ever circulating magazines." The plan of the ever circulating magazine is simple. Its staff of contributor and its readers are the same. Its staff may consist of a dozen, a score, or a hundred persons. Say that it commences with a score. The first of these, call him the conductor, writes a paper on some subject of interest, relating how, in using So-and-So's transcendent plates, ever negative was covered with comets, stars, and fog. This he forwards by post to No. 2, who contributes his experience on the same or some analogous subject, and, stitching it to the contribution of No. 1, sends it off to No. 3 who follows suit, and so on until the whole of the twenty have added something. It then returns to No. 1, who having read all which has been added since it left him removes his own first paper, adds another, and again sends the magazine on its travels, each one on receiving it pursuing the same course. Every paper thus goes through the hands of the whole and each one contributing. In such a magazine any form of grievance can be discussed because it is not published, and such a magazine furnishes a direct means of sympathetic intercourse amongst those who are working through similar difficulties. Our own pages provide, of course, a similar form of intercourse and intercommunication; but the more direct and more private means provided by the ever-circulating magazine would, however, more especially meet the wants of many. The stimulus to recording experiences afforded in such case would, doubtless, lead to the production of valuable papers of interest, to a wider public than those of the private magazine, and in such we should hope occasionally to secure papers for the interest of photographers at large.

NOVELTY IN PORTRAITURE.

An interesting novelty in portraiture appears in the recently issued number of Mr. Fitzgibbon's excellent *Practical Photographer*, under the name of the "statuesque photograph," introduced and produced by Mr. Landy, of Cincinnati, a portraitist well known in connection with pictorial effects in photography. The first impression the illustration in question conveyed to our mind was that it was a reproduction from a sculptured bust in marble. On examining more closely, we find that it is a portrait from a living model with considerable beauty of feature and form. The eyes are closed, and the rippling hair, which

is probably powdered a little, is arranged in classic fashion somewhat after that of the well-known *Clytie*. The face, which is taken in profile, is inclined to the shoulder. The camera stands behind the figure, a back view of the shoulders and neck being obtained, with the face, as we have said, in profile. Drapery in massive classic folds hangs round the lower part of the shoulders and bust. The pose and composition are full of classic repose, but the sculpture-like effect is most essentially dependent upon the skilful lighting, which, whilst giving the utmost roundness and modelling, is singularly soft and delicate, with exceeding tenderness in the shadows and reflected lights which suggests white marble. The principal light is apparently a concentrated top front light, which marks out the edge of the profile with a delicate line of light against the dark background. All the remainder of the face and figure is in a delicate mezzotint without a single black shadow or chalky high-light. The picture is printed in an oval medallion.

This style could never come into use for general purposes; but it is, nevertheless, a charming novelty, which may be found very useful in special cases where novelty of effect is desired and a suitable sitter is found. In any case, an example or two of such a style will give variety and interest to a collection of specimens.

THE MEDALS AT THE NEXT EXHIBITION.

THE following are the medals offered for competition at the next Exhibition of the Photographic Society. There are, it will be seen, twenty-six medals offered; twenty-three of which are for forms of excellence specially indicated, three being left at the disposition of the judges for any form of excellence which may seem to them to merit recognition, but which had not been specially contemplated by the Council. As there is, possibly, a little ambiguity in the statement as issued, we may briefly point out the intention. In many cases it will be seen "two medals" are offered "for the best landscape ten by eight and under, and above ten by eight;" "two medals for the best portraits twelve by ten and under, and above twelve by ten," and so on in other cases. The meaning is that one medal is offered for the best landscape any size up to ten by eight, and one medal for the best portraits any size up to twelve by ten, and also one medal for the best landscape any size over ten by eight, and one medal for the best portrait over twelve by ten. The aims for which the medals are offered, it will be seen, pretty well cover the ground of competition in photography:—

Two medals for those pictures which, in the opinion of the Jury, shall display the greatest general excellence.

Two medals for the best landscape, ten by eight and under, and above ten by eight.

Two medals for the best portraits, twelve by ten and under, and above twelve by ten.

Two medals for the best single figure study, twelve by ten and under, and above twelve by ten.

Two medals for the best enlargement untouched, and for the best enlargement and *negative* by exhibitor.

Two medals for the best *genre* pictures.

Two medals for the best photo-mechanical prints.

One medal for the best study from animal life.

Two medals for the best instantaneous pictures.

Two medals for the best six stereo transparencies.

One medal for the best frame of dry-plate photographs.

One medal for the best micro-photograph.

One medal for the best specimen of surface printing from metal.

One medal for the best apparatus.

Three medals will be placed at the disposal of the jury for any novelty or other form of excellence in process or result.

The awards will be decided by a jury consisting of seven members: the President of the Society; two members of Council; two members of the Society, not being members of Council; two artists of high reputation.

The names of the jurors will be announced to the Society when the gentlemen who may have been asked to serve have accepted the duty. To be distinctly understood that no award will be made where the works in competition are not of sufficient merit.

CARBON AGAINST SILVER.—A CHALLENGE.

SINCE the visit of Mons. Lambert to the United States, the controversy as to the respective merits of carbon and silver printing has waxed hot amongst American photographers. Our Philadelphia contemporary has placed itself in antagonism to carbon; *Anthony's Bulletin* and Mr. Fitzgibbon's *Practical Photographer*, without strong partizanship, giving carbon welcome and fair field. In the June number of the vigorous and healthy St. Louis journal, into which Mr. Fitzgibbon puts so much of his own vitality, a challenge appears, offered by Mr. James Inglis, of Montreal, a well-known skilful and successful portraitist, for a competition of carbon against silver, the stakes to be about one hundred pounds sterling. Here is the challenge as it appears in the *Practical Photographer*:—

"To give a practical turn to the wordy discussion that has been raging over the carbon processes of M. Lambert, I will offer a challenge to the advocates of silver printing who are non-licencees. The stakes to be \$500, to be deposited in a bank, to be decided upon by the officers of the N. P. A. The conditions of the contest to be as follow:—

"For the best photographic prints, for one or all of the Journals published in the United States (on condition that a remunerative price be allowed for the pictures).

"In the event of the journals not accepting the pictures for illustrations, the challenge shall then be for the best fifty chromotypes against the same number of silver ones.

"Should any of the journals accept the pictures, they shall appear simultaneously in the same journal for July or August. These being the two hottest months in the year are chosen to establish the fact of the practicability of the Lambertype and Chromotype processes in warm weather.

"The subject for competition shall be a bust of a man, woman, or child. The points for competition shall be softness, depth, and roundness, together with the artistic finish of the picture as a whole.

"The judges to be ten in number, and chosen by the officers of the N. P. A.—to consist of three non-licencees, two artists, two amateur photographers, and one chemist.

"I might have added a few more points for competition; for instance, that inside the mask of the picture should be full glazed, and outside matt finish; also a combination of different shaped masks and tinted borders, and the printing-in of the name and address. But as these complications might be more than a silver printer would care to trust himself on, and as I do not desire to put any obstacle in the way of an acceptance of the challenge, I forego those and many other points of excellence, knowing them to be beyond the range of silver printing.

"That photographers may not be deterred from investing in one of the finest processes in existence, I will here state, for their benefit, that I have only been working successfully about six weeks at these processes, yet I am confident enough to challenge those who have had from twenty to thirty years' experience in the silver process—thus, at least, showing my appreciation and confidence of this much-abused process."

FRENCH CORRESPONDENCE.

THE NEW LAW RELATING TO PHOTOGRAPHY IN PUBLIC MUSEUMS AND GALLERIES—ONLY THE DRY PROCESS ADMITTED—A GOVERNMENT PHOTOGRAPHIC ESTABLISHMENT—

TOBACCO AS A PRESERVATIVE FOR DRY PLATES—WHAT IS WANTED IN THE FORM OF A PRESERVATIVE.

THE Minister of Public Instruction has just taken a step which will prove of the highest importance, not only to

photographers, but to students, writers, artists, savans, &c. By an Act which has just been published, bearing date the 1st June, in the *Journal Officiel*, the doors of all the State collections have been opened to photography—libraries, archives, galleries, museums, art collections, &c. Till now, access to these establishments was but rarely accorded to the camera, and only those armed with very special recommendations were permitted to secure photographs, so that any general work was rendered impossible. The result was, that the most valuable documents and treasures were kept guarded and locked up from the public, for the camera, which could have reproduced the treasures, and placed them within reach of all, was forbidden in the State collections. This exclusiveness has, in the end, brought about the abolition of so absurd a custom. In the first instance, the photographers admitted in the public libraries having only the wet process at their disposal, and taking but little precaution in the use of it, were culpable of many acts of carelessness and injury, and, what is worse, sometimes damaged to no little extent the valuable documents which were entrusted to their care to reproduce; no wonder, perhaps, after this, that it was decided that photography was dangerous, and ought to be excluded in future. But although since then more skill has been acquired, and processes have been modified, so that now dry plates may be used with much certainty, the edict that photographers should not be admitted to the public galleries has remained in force. Some of my readers who visited Paris twenty years ago, and went as far as Versailles to look at the Palace and Gardens of that beautiful suburb, may have remarked before the facade of the Orangery a sentinel mounting guard over that spot, where there was, in truth, nothing to guard. One fine morning a journalist with a thirst for knowledge spoke to the sentinel and asked him the reason for his presence. Getting but an unsatisfactory reply, the persevering enquirer referred to the Governor of the Palace, and at last discovered the reason. It was this: At the time of the restoration of the Palace in 1820 the facade of the Orangery was repainted, and to prevent the public, which on Sundays and fêtes is somewhat numerous, from rubbing against the wet paint and otherwise injuring the work and their clothing at the same time, it was decided to place a sentinel in the vicinity for a short time. But the order having once been given no one troubled themselves about rescinding it when the paint had dried, and the consequence was, that for some twenty-five or thirty years afterwards a sentry still continued to tramp methodically to and fro before the Orangery every day.

There is a good deal of analogy between this anecdote—whose authenticity, by the way, I should not care to guarantee—and that which has taken place in respect to shutting out photographers from the State collections. It has taken some time to get to know why the camera was originally excluded, and now we find that the original cause has long since disappeared. Thanks, however, to the recent decision of the Minister of Public Instruction, any one who desires to reproduce an object contained in one of the public galleries or museums may secure the desired permission to enter the building; he must of course conform to the regulations which have been drawn up for the guidance of photographers, and these contain a clause to the effect that he must always make use of a dry process in operating. Operators must bring with them plates or tissue ready prepared, and must do nothing farther upon the premises beyond exposing their plates, the development and fixing of the latter being conducted subsequently at home. At the present day the conditions to be fulfilled are indeed very easy to fulfil. There is to be fitted up in each establishment a studio where exposures may be made, and this apartment will be so arranged as regards lighting, &c., as to give the most satisfactory results in every respect. Every photographer who is admitted to the privilege must forward to the director of the establishment good negative and two prints of every object reproduced

by him in the gallery or museum. In this case, in the event of the original object being one day injured or destroyed, the State will still be in possession of an exact copy of it. As to the two positive prints, they are to be referred to thereafter in preference to the originals in any case where the latter are not absolutely indispensable.

In this way everybody bids fair to gain by the new regulation. But this is not all. The Minister at the same time has decided that there shall be established in the Ministry itself a laboratory for the preservation of the clichés deposited in the manner I have indicated. In this photographic establishment will be executed all the photographic work for the State, while again it will serve for the instruction in manipulation of those charged by the Government with scientific missions, and also for the testing and verification of any apparatus and chemicals to be sent abroad to missionaries and others. Here, then, is certainly a step which cannot fail to bring forth good fruit.

M. Terperau, the skilful Bordeaux photographer, has devised a means for carrying liquids in the field, which consists of a cylindrical case of cardboard covered with waterproofed canvas. It has the advantage of preserving the bottle from the dangers of collision, and permits one to employ the liquids without soiling the fingers. It is an invention to be recommended to tourist photographers.

An excellent work upon preservatives has just been completed by M. Boivin, who in a letter to me expresses himself upon the subject as follows:—"A preservative little employed, but which, nevertheless, merits serious attention, is tobacco. It rivals all I have experimented with, and gives the most satisfactory results. It exalts the sensitiveness of the plates to a very high degree, and it prevents the plates from fogging and solarisation. Unfortunately, the solution is subjected to sudden change, but the labour of its preparation afresh is compensated for by the beauty of the results furnished. Here is the formula:—

No. 1.—Water	80 cub. cents.
Ordinary smoking tobacco	5 grammes.
No. 2.—Water	20 cub. cents.
Gum arabic	2 grammes.

The tobacco is first of all rapidly washed in cold water, and after being drained upon filter paper, it is boiled for the space of a minute in eighty cubic centimetres of water in a glass flask over a spirit lamp. The decoction is permitted to cool, and is then filtered. No. 2 solution is added, and you filter again. A piece of camphor may be added (powdered) to add to its keeping qualities, but this addition is not to be recommended. This preservative is poured several times over the film, which has been previously sensitized and washed; the film is subsequently washed again, and permitted to dry. The last washing is very important, for if this is not effected the sensitiveness of the film is considerably diminished. Washing before development is not necessary. To resume: after having essayed the alkaloids, and a large number of basic and neutral substances, as preservatives for bromide films, M. Boivin has found little difference in their preservative properties. What fails, and what is wanted, is an accelerating substance which would endow plates with extreme rapidity. This would, according to him, be some inert organic substance susceptible of absorbing the bromine set at liberty by the chemical action of the luminous rays during the exposure of the film to light.

ERNEST LACAN.

PHOTOGRAPHY AT THE PREFECTURE DE POLICE AT PARIS.*

It is some time since photography has been made use of in the interests of the police and justice. The rapidity of the processes, and the rigorous exactness of the results which the art furnishes, render it too valuable an aid to be neglected. For some time, however, it was any photo-

* *Le Petit Journal*.

grapher, more or less skilled, to whom was left the execution of this judicial work; but the numberless inconveniences of this plan of proceeding caused the camera, after a while, to be used only in the most urgent cases, notwithstanding the great advantages which proceed from its employment.

In 1854 M. Moreau Christophe, then director of the central establishment at Eusisheim, made the proposition that all the prisoners should be photographed immediately prior to their discharge. To the portrait was annexed an account of the individual, biographical notes, and some extracts of the proceedings taken against him. The importance of making a collection of this description may well be imagined; but, nevertheless, no decision was come to in the matter, and it remained in the form of a proposition.

In 1871, at the time of reorganization which followed the disasters of France at the close of the Franco-German war, a man of considerable energy, who had earned the right of making himself heard (M. Lombard, a peace officer), obtained from one of the *prefets*, whose spirit of progression was well known, the necessary authority to form a small photographic service, to be employed upon the most urgent business connected with the police.

A very modest equipment and store of materials were acquired, and the charge of these given over to two police officers, who were detached from their ordinary work for the purpose. A suitable *locale* was secured in a disused police station, and the same properly fitted up. It was not long before the value of this improvement began to testify itself. M. Voisin, who succeeded M. Leon Renault as *prefet*, did not show himself less interested in the success of the new department, and by degrees the staff confided to the care of M. Lombard was augmented, and the establishment soon acquired significant proportions. Work was not wanting for it to do.

At the present moment the photographic establishment of the Paris police includes eight operators, or special employés; it is complete in every way, except that the staff and *matériel* at disposal are still somewhat insufficient, seeing the multiplicity of the work to be performed, and the urgency that frequently marks the operations to be carried out. As to the *locale*, it consists of several apartments in various parts of the building.

There is, first of all, a studio where portraits are taken, in a garret near the *Palais de Justice*, and another in connection with the Morgue; the latter studio is on a terrace upon one of the houses of the quai. At the Prefecture itself, in the quarters of M. Lombard, is to be found an apartment where paper is sensitized, the printing is conducted, and the pictures retouched and mounted; and, finally, a cabinet near at hand contains all the negatives properly classed and put away in big cupboards; these are the archives.

The work going on is incessant, and is executed with an order and precision which nothing seems to disturb. Every evening the Director of the House of Detention sends in the list of individuals who have been remitted to his charge during the day, and whose arrest is provisionally decided upon. M. Lombard extracts from this list the names of all who are known to be bad characters, which are designated assassins, thieves of various character, escaped convicts, and so on. In each case he fills up a form, which serves the prisoner as an entrance-permit to enable him to visit the portrait studio. All these forms are sent to the photographic establishment, and the work of the latter is arranged for the morrow. At an early hour in the morning the work begins, the prisoners filing in according as their names appear on the list. Each prisoner corresponding to the form previously filled in is taken from the House of Detention behind Sainte Chapelle, and, escorted by policemen, he crosses the courtyard, and after numerous detours ascends the stairs which lead to the studio.

Arrived at the studio, the policeman in charge of the

criminal delivers the form in which the man is identified, and all being in order the escort receives a receipt for the prisoner. In less than half a minute two portraits are taken of the model—one full-face and the other profile—and the sitter is then passed on, and another taken in hand.

The process of photographing is a very summary one. The studio has not twenty superficial metres; the roof, very much inclined, is replaced at one side by a glazed frame, which permits a very bright light to pass, striking the model very closely; two operators, one placed in an alcove screened by a dark curtain preparing the plates, and the other in a recess to develop and fix the negatives, work on uninterruptedly, while a third photographer poses the prisoner, and takes two portraits of him. There is always a plate ready, and the lens is always focussed, so that not an instant is lost. The average number of double negatives taken in this studio is from thirty to thirty-five daily.

When the day's work is done, the printed forms are collected, and they are arranged in alphabetical order in long boxes, where they remain until impressions from the negatives have been secured, so that no mistake or oversight can occur. It may be easily guessed of what value are these records, thus taken daily, from a judicial point of view, and as regards public safety. But the functions of the police photographic department does not end here. As soon as a murder is discovered, and the remains of the victim have been transported to the Morgue, a photograph is taken of the murdered man or woman; further photographs are secured of the scene of the murder by the police photographers, in case such representations may hereafter be required in the courts of law for submission to the jury. The acts of conviction are in like manner photographed. Bodies at the Morgue which fail to be recognized by friends or acquaintances are also photographed before they are buried, and these anonymous and posthumous portraits, added to the registry of the lugubrious establishment, place it in the power of the family or absent friends, on presenting themselves afterwards, to recognize a lost friend or relation.

Notwithstanding the disadvantages under which the little staff labours—the surfeit of work, the inconveniences of the improvised apartments, and the unfavourable conditions under which the greater part of the operations are conducted—the results obtained by this new branch of the police force are exceedingly satisfactory, while many of the portraits would do honour to the most skilful photographer. Some views recently taken of scenes made notorious by criminals—those notably of Godfrey's house at Neuilly, of the building in the Rue de Boulogne, the Ducourtieux Pavilion, &c., which measure not less than forty by thirty centimetres—are pictures of a first-class order. In the case of interiors the objects are so dark that recourse is necessary to magnesium light and other artificial illumination; but despite these attendant difficulties the police photographers always manage to secure satisfactory results.

NOTES FROM THE EAST.

BY W. WILKINSON.

As carbon printing seems to be the engrossing topic of the day, I hardly think I can do better than give my experiences in the East.

Within a week of landing in Ceylon, I tried my hand at the production of carbon transparencies. My first essay was to sensitize sufficient tissue to print twelve cabinet pictures, and the first I developed yielded a fine picture, but that and another were all I got from that batch. I set my wits to work, and soon found out where the hitch was, and the next batch was much better.

The next stage was to make some enlarged negatives, to do which I dissected the elaborate enlarging camera that had been sent out from England some two years previously; my dissection consisted of dispensing with about

thirty pounds weight of rackwork, and also of a twelve-inch condensing lens, and the substitution of a piece of coarse ground glass.

En passant, I may mention, for the information of the sceptical, that the wooden bath I brought out with me, lined with Bates's black varnish, answers out here just as well as it did in England, and that one gallon of bath that was in it for one month worked just as well as it did before being put in.

After securing the enlarged negative, my next step was to secure prints by the single transfer process; but here I met with a tremendous check, although I treated the tissue the same as I had done that for transparencies. All went on apparently satisfactorily until I came to the development of the print, when, instead of the backing alone coming away from the final support, the whole of the tissue stripped off, leaving the transfer paper quite clean. Again I had to commence experimenting, and after a lot of trouble I got everything all right, and now can produce prints in carbon with as much ease and certainty here as in England, even now in the hottest time of the year in Ceylon.

When in England, many of my friends who produced their own carbon transparencies were continually grumbling at the pigment in the tissue not being properly ground or filtered, and, as a consequence, the transparencies were full of specks. My first two or three batches were the same, but as I knew the tissue was hardly to blame for all the specks, I carefully filtered the bichromate solution, and also the water used for wetting the tissue previous to mounting the same upon the glass used as final or developing support, and the result was as I expected—transparencies perfectly free from specks or spots of any description, thus pointing at once to the fact that dirty transparencies are the result of carelessness in the manipulations after the tissue leaves the Autotype Works, rather than in the manufacture of the same; and if photographers in experimenting with the carbon process would only bear in mind, when failure ensues upon the first two or three trials, not to blame the tissue, but to alter the mode of working, and to work carefully and methodically, the difficulties of carbon printing would melt away into thin air very quickly.

As regards the tissue, I can say (from personal and from practical experience) that as sent out from the Autotype Works it is always good, and if properly manipulated will produce as good results as that used by the Autotype Company, which, as your readers know, are better than the best silver.

Now I am writing, it may perhaps interest your readers to have some description of photography as practised in Ceylon. Although within a few degrees of the Equator, the thermometer is rarely higher than ninety, and except just in the middle of the day there is not much difference in the practice of photography here and in England—in fact, using Huggon's collodion, I find no difference. Exposures, I fancy, are a little longer here, on account of the violent contrasts. In the dark tent it is very hot indeed, although not oppressive, like the summer heat in England. Coolies (clothed almost in the disgraceful costume of the Greek slave) do the heavy work, and start some time before the operator (he following in a carriage, as it is much too warm to walk far): and as one who always takes charge of the tent has had about ten years' experience, he is a splendid help, getting everything ready for work, and packing up again when work is over, in a style that would shame the most intelligent British labourer, making outdoor work a pleasure instead of being a bore.

One day, in stock taking, I came across a lot of old silver watch cases, and proposed to convert them into silver nitrate, which was soon managed by dissolving in nitric acid; then, after evaporating to dryness, and fusing, I dissolved the residue, and made a solution thirty grains to ounce, a splendid *pea green*; and upon iodising a

portion, and trying a plate, I got a splendid negative, and enclose you a couple of views taken with the identical bath during a gale last week, when the light was none of the brightest.*

On March 30th Mr. A. L. Henderson gave a formula for a developer which hits exactly upon a principle I have been trying to get at for three or four years, but never to my satisfaction, viz., perfect compatibility (in the matter of equal density) between bath and developer. So when I saw Mr. Henderson's formula, I at once tried it, and am very pleased with the result in every way, and so also are three other photographers to whom I have given the formula.

When on my voyage out here, I went ashore at Aden, and called upon a photographer there, and was rather astonished to see a large bottle of distilled water from England to make the negative bath. I set to work, and showed him how to make common water do, by adding a few grains of silver and a few drops cyanide solution to a Winchester of water; and as I had to leave Aden same evening, I left instructions how to proceed after sunning and filtering, viz., adding rest of silver to make bath up to thirty grains to the ounce, and about ten grains of nitrate of baryta; which instructions have been carried out (as a letter I got the other day informs me) with perfect success. This I mention merely to show that cyanide of potassium and nitrate of barytes are perfect remedies or adjuncts, even in the hands of a novice.

TINTED PAPERS FOR PHOTOGRAPHS.

BY J. L. GIBON.

In the course of some details of photography in the late Philadelphia Exhibition Mr. Gibon says, in the *Philadelphia Photographer*:

"I had almost forgotten to make an intended remark in regard to the use of tinted papers. I believe that I have finally come to the conclusion that the pure white surface is the most desirable for photographic purposes. After running in a rut for a number of years, anything that is new is apt to captivate us, and for the time being we imagine excellencies to have been attained that do not really exist.

"Since my return to the legitimate portrait department of our art I have given considerable thought to this one item. In my old practices as a water-colour painter of 'landscapes and seascapes,' I had been taught the habit of first washing over or tinting the papers with some combination of warm colours. The 'principle' was the same as that which induces the photographer to use the pink instead of the white surface. It is claimed that harshness is prevented. I am inclined, however, to fall back upon old authorities, and claim precedence for the purity of the lights. The tinted papers, as we usually receive them, soon become, after being worked, only dirty-looking substrata.

"At one time, years ago, I made rather a pretty class of picture, adapted to the larger size, in which the face, hands, and all of the real lights of the picture were kept perfectly pure, and the remaining portions were stained. Exposing the 'ways that are dark,' I will confess the method then used. After the photograph was printed, toned, and partially washed, I would cover the portions that I desired to remain unaltered with rather a heavy, normal collodion. Afterwards I would immerse the print in a solution composed of an 'extract of madder,' brought to a pinkish colour with a free use of alum and water, heated. Of course, for awhile, the making of the picture was quite remunerative to me, as being a novelty in photography. Others of our brethren, however, commenced to imitate, and stained their papers with all sorts of solutions.

* Two fine instantaneous photographs of a stormy sea and rough breakers are enclosed.

"Their practices were as bad as those of the dry plate workers, because I know that they brought 'coffee, tea, and ale,' into requisition. Some of the results were ludicrous, and the general average of the attempts was bad."

Correspondence.

DALLASTINT.

DEAR SIR,—I have again to thank you for favourable notice of my work.

The only point in the article in your last issue I wish to correct is, that you seem to have a doubt as to the rendering of foliage in landscape. There is not the least difficulty. If the foliage is well rendered in the negative, it must come right in the Dallastint plate or block.

Dallastint typographic is the very same process, with sundry modifications, as the photo-electric process by which the "Kenilworth" subject you presented to your subscribers in 1864 was done.

I have no idea yet of "resting from my labours." I have wished to "crown the edifice" with colour. This I think I have succeeded in doing in my process yclept "Chromo-Dallastint." I have produced by means of it, and in four workings at letter-press, an imitation of a sepia drawing. This is in reality a more trying test than a subject in polychrome. I have experiments in progress in the direction of colour work which will, I trust, convince the most sceptical of the capabilities and value of Dallastint.

Again thanking you for the interest you have always shown in my work, and your readiness to record my progress,—I am, dear sir, yours truly, DUNCAN C. DALLAS.

362, Gray's Inn Road, London, June 18th.

PS.—The sepia subject will be among my exhibits at the Carlton Exhibition.

VOIGHTLANDER'S NEW LENS.

SIR,—Referring to the new lens by Voightlander which I had the pleasure of introducing at the last meeting of the Photographic Society of Great Britain, permit me to state that I did not say, as you have reported, "the new lens resembles the rectilinear;" I said, "in outward appearance it resembles the rectilinear." This statement of course referred only to its size, weight, and general appearance. As the new Euryscopic lens will be patented, the entirely new principle on which it is constructed will soon be made public, and I need hardly say that, as regards its principle of construction and the work it is capable of performing, the new lens is quite unlike any hitherto made by opticians, either in this or any other country, notwithstanding the statement made by Mr. Stuart (Rees and Co.) to the contrary.—Your obedient servant, R. W. THOMAS.

COMMERCIAL DRY PLATES.

SIR,—You have done good service to the photographic world in publishing the correspondence between Mr. H. P. Robinson and the pirate painter of the Dudley Gallery. Half the value of journalism is in the public exposure it gives to roguery and imposture.

There are other matters also of great importance to photographers requiring some ventilation in the journals, and one of these is the number of abominable commercial dry plates issued by some so-called dry plate companies. I saw in your report of the last Liverpool Photographic Society's meeting that some negatives on these plates were shown of great interest as regards the subject, but utterly spoilt by the bad manufacture of the plates. The names of the makers were (unfortunately) not given. It would certainly be well that those who use these plates should communicate to the different photographic societies both the virtues and faults of plates made by the now so much vaunted emulsion.

The best emulsion I have yet found is the Liverpool, which I find quite good after two years' keeping; but I have had lately numerous bad plates from a "company" whose plates were formerly near perfection.

Mr. Warnerke has written a valuable paper in your last YEAR-BOOK on the cause of spots in emulsion, and he put down seventy-five per cent. (as I understand his paper) to preventable faults in the emulsions and in coating the plates. I believe gross carelessness is the cause in those who prepare the plates in most instances.

We have no photographic society in Bedford, the town being in a semi-savage state as regards modern science of most descriptions. When some months since I brought before the notice of the Bedfordshire Natural History Society some dry plate transparencies, carbon prints, and a pocket camera and lenses, the savans of that learned Society appeared to look on these scientific instruments, and pictures produced with them, much as Robinson Crusoe's man Friday looked on the gun which had slain his black brother. I fear, therefore, I cannot look for aid in determining the faults in dry films—commercial or otherwise—in this locality.

Can the Photographic Society of Great Britain (or some other important photographic society) aid a poor outside photographer in such matters as crops of spots, and stars, and other faults in dry plates? For the last eight years I have been a member of the Parent Society, but have not been able to attend more than one of its meetings, and only this year resigned membership.—I am, sir, your faithful servant, Bedford, June 19th. FRANCIS W. TURTON.

PORTABLE STUDIOS.

DEAR SIR,—Having to erect a temporary studio at a place which I visit for three or four months each year, I should feel obliged if you or any of your readers would inform me the best method for so doing. The instrument I use for my work (portraits) is a No. 2a Dallmeyer's, so I require a length of little less than thirty feet for groups. I should prefer a ridge roof, but require the dimension for the light, and the most economical method of darkening the remainder. Could a tent be made ready for throwing over a frame, and what would be the cost?

I would suggest that any of your advertisers having small articles that would come through the post should advertise the price, including postage for the Colonies (Australia and New Zealand), as it is next to impossible to obtain any small novelties from dealers in these places. Apologising for troubling you,—I remain, dear sir, yours faithfully, HERBERT HY. VOULEY.

Westport, West Coast Nelson Province, New Zealand.

[Our correspondent will obtain some valuable hints from a letter in a recent number.—Ed.]

INACCURACY IN PORTRAITURE.

SIR,—I watched the last two weeks' issues of the News with much interest, hoping your article upon "Inaccuracy in Portraiture" would elicit a good deal of discussion, considering its great importance; but to my surprise it seems to have attracted no notice whatever.

Being engaged very largely in photographic portraiture, I have many opportunities of verifying all that your correspondent states; and so great is this difference between prints that it occasionally happens that a customer will select from a parcel of cartes and cabinets all the long or broad faces as the case may be, and return them with many sarcastic observations as to the so much talked of "truthfulness" of photography.

This appears to be almost entirely a paper maker's question, but unless some remedy is devised by the manufacturer or albumenizer, I fear that, between excessive retouching, and this far worse evil of unequal expansion and contraction, our art will fall into such disrepute that a return to the old silhouette or scissor-type will be almost preferable.

Perhaps some plan analogous to Mr. Sutton's method of resinizing, previous to albumenizing, might be found efficacious.—Yours, &c.,
JANUS.

Proceedings of Societies.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

The new Board of Management's first monthly meeting was held at 174, Fleet Street, on June 7th.

The minutes of the third annual meeting having been read and confirmed, the election of the following gentlemen took place:—Mr. Cassinello as honorary member, Messrs. Green, Alder, and Milliard as ordinary members of the Association.

A resolution was then brought forward, proposed by Mr. J. Fage, seconded by Mr. Sisman:—"That all members' subscriptions, whether honorary or ordinary, shall date from the first day of the month in which they were elected, and be payable in advance. The Secretary to notify members to that effect as their subscriptions become due."

Proposed by Mr. Sisman, supported by Mr. Fage—"That the Secretary shall forward all monies above a stipulated amount to the Treasurer on the second Monday in each month."

The members of the Sub-Committee elected to carry on the duties of secretary, pending the election of secretary, then presented their balance sheet. After being carefully audited, the meeting passed it as read; thereupon the books, &c., were handed to the new officer.

After grants had been voted for the several purposes of the Association, a vote of thanks was tendered to the Sub-Committee. The meeting then adjourned till Thursday, July 5th.

Talk in the Studio.

POPULARIZING CARBON PRINTS.—We have received from Messrs. Wolsenholme, of Blackpool, a hint of the method they are adopting to popularise the "chromotype" or carbon print. They issue a circular briefly explaining the claims to permanency of the chromotype, and enclosing for acceptance a charming example. The prints used for this purpose are preferably pretty portraits of children. These are generally preserved and placed in an album, where, as a rule, they contrast favourably with the silver prints—probably many of them more or less faded—and so prove an admirable advertisement.

"TISSANDIER'S HAND-BOOK OF PHOTOGRAPHY."—Messrs. Sampson Low and Co. have in the press, and will publish shortly, a second and revised edition of "Tissandier's History and Hand-Book of Photography." Besides containing a more complete account of the part belonging to Englishmen in the discovery and improvements in photography, there will also be an additional chapter by the Editor, embodying the latest results obtained in the various branches of the art, thus bringing the work down to the present time. It will also contain, in addition, specimen prints by the "Woodbury," "Permanent Ink," "Lichtdruck," "Albortype," and "Zinc Processes."

IMPROVISED BURNISHER.—A correspondent of the *English Mechanic* says:—"Amateurs who have not a photo-rolling-press can put a first-class gloss on their C.D.V. by the following means:—Got from an ironmonger or zinc-worker two pieces of sheet zinc, size about 4½ inches or 3½ inches (it will have a splendid polish if new, and cost about twopence); screw your wauling or wringing-machine rollers down, place your C.D.V. between the zinc plates, and roll the same between the rollers. When the C.D.V.'s come out you will find that they are glossed. If you warm the top plate, you will find a superior gloss on. If you get two polished steel plates you will be able to gloss your C.D.V. equal to any rolled with a photo press. You can get a finer gloss by warming the plates. If you should be out photographing, and spill part of your sensitising solution, so that the plate is not covered, you will find that by placing two or three clean glass plates behind the dipper your solution will cover the plate. Of course you can dilute your bath a little, too."

A NEW PHOTO SCULPTURE PROCESS.—In the United States Army Department at the Centennial there was exhibited a handsome model of the Rock Island Arsenal. It is to be regretted that this work of art did not bear some description as to the manner in which it was produced—an explanation of

which we find for the first time in the recently issued report of the Chief of Ordnance of the United States army. From the various buildings, it appears, positive photographs were obtained, representing all their different sides. Each view was then exposed over a thick film of sensitized gelatine, covering a glass plate, and afterwards the soluble, opaque portions of the gelatine were washed out. The film was then swelled by a peculiar process, so as to magnify its differences of level, until a suitable relief was obtained; and a plaster cast being taken of the film, it gave a permanent mould from which many repetitions could be made. A successive series of these plaster views, taken from the different sides of a house, were mitred together at their edges; and when roofed in they formed a perfect reproduction of the house itself, every stone and crevice being represented. In one building the slats of a lattice work around the piazza were plainly exhibited, in lines not over 0.006 inch in width. The model was made by Baron F. Von Egloffstein, of this city.—*Scientific American*.

To Correspondents.

KLARY'S SYSTEM OF LIGHTING.—We continually receive enquiries regarding the pamphlet which M. Klary, of Algiers, offers to photographers, describing his system of lighting. Two correspondents make enquiries this week. As M. Klary's system is supposed to be a secret, we could not with propriety publish details, even if we had his pamphlet before us. We have not, however, seen it, and only know of his plan from the information sent by various correspondents. We understand that M. Klary's system depends chiefly on the use of portable screens, and on page 126 of our last volume we gave full details of the use of screens after the fashion in which we understand they are employed by M. Klary. As to whether the pamphlet is worth the fifty francs charged for it we are not in a position to say; nevertheless, we believe it contains many valuable hints.

W. W.—Ammonia sulphate of iron is doubtless meant.

TISSUE.—By the use of a revolving background a peculiar softness and atmospheric quality in the background of the picture are supposed to be secured. There are various modes of securing the revolution. Sometimes a rapid touch of the hand secures sufficient revolution for each sitting.

J. M. G.—D.—See an answer above.

J. J. T. G.—The spots on the negative are doubtless due to turbid particles at the bottom of the bath, stirred up, and brought into contact with the film whilst flashing out the plate which had slipped off the dipper.

B. F. M.—Either loaf sugar or crystallized sugar-candy will answer; about thirty grains in each ounce of the developer. It acts as a restrainer both mechanically and chemically. Some years ago we reported a somewhat extensive series of experiments with various forms and proportions of saccharine matter in the developer. Treacle acted as a most powerful restrainer.

M. D.—The addition of glycerine to the nitrate bath materially checks the drying of the film in long exposures. It is important that the glycerine should be pure, and that the bath should not contain free nitric acid. Failing these precautions fog is apt to ensue. No fixed proportion has been settled. We should try a small quantity at first, and add more if necessary. One ounce of glycerine to a pint of silver solution would be a good dose, we should think. Wet blotting-paper placed at the back of the plate has been found useful.

TROUBLED.—We could have given you a more certain opinion if you had sent an example of the trouble; but from your description of the faint flat print it seems probable that the paper has been too dry when placed in the frame. If sensitive paper is used absolutely bone dry, and the pads placed at the back of the paper are in the same condition, printing is slow and imperfect, the image being faint, grey, and flat. The paper must not be so damp that it will stick to the negative, neither must it be absolutely desiccated.

G. D. (Yarmouth).—There are no means of restoring old insensitive collodion to its pristine sensitiveness. It may be improved by the addition of a bromide, say to each ounce of collodion one grain of bromide of cadmium. The best mode of using such a collodion to advantage is to add a little of it to a new colourless collodion, which is often apt to fog. A small portion of the older sample is often a great improvement.

W. DAVEY.—Thanks.

F. NAIEN.—New Zealand. We will institute enquiry. The fault is, we fear, with the colonial postal authorities. The copies are all duly posted here. We will hand your instructions and remittance to the publisher, and see that they receive attention.

JAMES H. CORSCADEN.—Inquiries are made for address, which did not appear in the communication made in our columns.

Several Correspondents in our next.

The Photographic News, June 29, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

FRANZ HANFSTAENGL, PHOTOGRAPHER—OUR CONVICT SITTERS.

Franz Hanfstaengl, Photographer.—The particulars of Hanfstaengl's life furnishes one more corroboration that success in photographic portraiture depends upon the photographer possessing art ability. Too often has the value of art knowledge been under-estimated in photography, and there are those who would have us believe that things photographic cannot be artistic. No picture secured in the camera can be, in the eyes of some people, a work of art at all; but let the photograph be accurately copied with the brush, as was the case with one of Mr. H. P. Robinson's pictures at the Dudley Gallery lately, and then there is no reason why it should not be received in any art gallery in the world. Those practised operators, again, who scorn having anything to do with art, and deem it quite sufficient if they supply the public with cheap and shining portraits, may also be assured that they will never get beyond a certain barrier, unless their pictures are executed in accordance with the canons of taste, for, look where you will, the portraits which have made the most way in the world will be found to emanate from men who are artists before they are photographers. Some time since we referred to this fact in these columns, and cited the cases of half a dozen men of European reputation who showed that they were all of them capable artists with pencil or brush as well as with the camera. Hanfstaengl, whose death took place two months ago at Munich at the ripe age of seventy-three, was no exception to the rule. His name, especially ten or fifteen years ago, was a household word among German photographers, and there were not many in this country who had not heard his name and admired his work. Hanfstaengl was known everywhere, and English visitors coming back from the Fatherland with portraits of themselves or friends, pictures taken in Dresden, Berlin, or Munich, served to keep the name fresh in the memories of those who could appreciate good work. The familiar name of Hanfstaengl was met with more frequently than any other upon the charming little *cartes* that reached this country from Germany, and the success of the artist may be guessed from the establishment in his name of different studios in several cities of Germany. Hanfstaengl made a way in this world for himself, and, as the *Art Chronicle* of Germany says, from an ignorant peasant lout, worked himself into a finely-cultured cavalier. He held the position of Hofrath, equivalent almost to the rank of a privy councillor with us, and had received much attention from the Prussian Court, King William the Fourth presenting him on one occasion with a snuff box with the Royal likeness upon it set in diamonds. This gift appears to have been of some value to the artist, for during the unfortunate time of 1849, when Hanfstaengl resided at Dresden, the ringleaders of an *emeute* were traced to his house, and he among others were led out by the Prussian soldiery to be shot. At the critical moment he bethought himself of the Royal present, and handing it to the officer in charge of the party, begged the latter to return the gift to his Royal master after Hanfstaengl's death—a proceeding which at once caused the release of the prisoner. Hanfstaengl, it appears, was born on the shores of one of those pretty lakes which constitute the southern portion of Bavaria—so charming a holiday ground—and came to Munich in 1816 an ignorant peasant boy. Resolved to make his way in the world, he attended the drawing and art schools in the town, and at the age of twenty-one was fortunate enough to attract the attention of Senefelder, who was, as our readers know, the discoverer or inventor of lithography. Hanfstaengl's art knowledge and skill as a draughtsman at once made him an apt

assistant, and in 1834 he journeyed to Paris, there to study Lemercier's method of printing from stone. Returning to Dresden an accomplished artist and lithographer, the idea struck him to reproduce the principal objects of art in the Dresden Gallery by the aid of the process he understood so well, and the King of Saxony having given his sanction, Hanfstaengl set to work to copy some of the principal cartoons and pictures upon stone. That he was, however, something more than a clever copyist is proved by the circumstance that he drew in his lifetime thousands of portraits direct upon stone, many of which rank among the highest works of this class. Few artists, indeed, could secure so rapidly and effectively the features of a model, for he at once seized the main points of a portrait, while at the same time he knew how to do so in a highly artistic way. Hanfstaengl was one of those to busy himself with the electrotype process, and established in Munich, between which town and Dresden he seems to have spent most of his life, an electro-typing atelier, therewith further to reproduce objects of art; and it was while so engaged that the advantages of photography struck him. He forthwith gave some attention to chemistry, in order the more to understand the manipulations of the process, and his art-education at once placed him in the first rank of photographers. As a reproducer of oil-paintings by photography he won a high reputation, this branch of the art being, as every photographer knows, a peculiarly difficult one, while, as we have seen, as a portraitist, he was simply *facile princeps*. It may be mentioned that in the reproduction of some works from the old Pinakothek in Munich (one of the chief State Galleries), Hanfstaengl was pronounced to have succeeded better than other twenty-two competitors in the matter. It is something to know that his labours were not in vain from a commercial point of view, for although we possess no information whatever on the subject, we feel sure that, in a business sense, as well as in that of art, he was a successful man. It is impossible that a photographer who enjoyed a European reputation, and whose pictures were to be frequently found in albums throughout this country, could have failed in securing for himself and his family a comfortable fortune. We are glad to hear that he leaves behind him those who, by reason of their artistic ability, are competent to maintain for the name its present honourable position.

Our Convict Sitters.—Some of our readers may be struck with the account which we published last week of photography as it is practised by the police at the Prefecture at Paris. It is a commonly conceived notion that you cannot photograph a man without his will, and with prisoners, it would be generally supposed, some resistance would be offered. But in the account we published, and which is translated from a popular Paris journal, *Le Petit Moniteur*, there is not a word to lead one to imagine that the prisoners resented the process of having their likenesses taken. In fact, no time seems to be allowed for any such contingency, and the criminals are filed into the studio one after another in quick succession. The operator is standing with a double plate in his hand, and apparently before the prisoner is well aware what is going on a front view, and one in profile, has been secured. It would be interesting to learn whether in this country there is now less opposition than formerly on the part of prisoners to be reproduced by the camera, for, if we remember rightly, some particularly clever contrivances were resorted to, in the early days, to overcome the occasional shyness and backwardness evinced by models to sit for their portraits under these circumstances. Now we believe the practice has been hit upon to have the picture-taking done immediately before dinner, and the early distribution of this meal thus depends upon the resolution of the prisoners to get over their scruples to sit still in the posing chair. But we fear that the British convict has not yet learnt to treat the affair with such equanimity as his French brother evidently does.

NOTES ON THE THEORY AND PRACTICE OF EMULSION PROCESSSES.

BY HERBERT B. BERKELEY.*

I SHALL be glad if the foregoing remarks on some of the theories connected with emulsions receive plenty of criticism from the members present this evening. If photography has hitherto advanced so rapidly, may we not expect even greater things when its mode of working is thoroughly understood? I will now leave this part of the subject, and make a few remarks on emulsions from a practical point of view.

Of course an emulsion cannot be too rapid, provided it work in a satisfactory manner. A very good quality of collodion emulsion may be made by a formula of Captain Abney's I published a short time since in the *British Journal*. The zinc bromide gives a very opaque film, most valuable for preventing blurring, and doing away with the necessity of backing or dyeing the plates. It is worthy of notice that Captain Abney obtains by his method an emulsion perhaps three times as sensitive as those I have prepared when presumably following his instructions. We have not yet been able to account for this difference; and I hardly think the methylated spirit can be the cause, as it gave with gelatine as sensitive a film as the rectified alcohol. I have prepared an emulsion without albumen, and another with two grains of albumen to every eight grains of pyroxyline, yet I do not find there is much appreciable difference between them.

My emulsions are very opaque; and if the film be partly dissolved by hyposulphite of soda it is easy to see that the colour by transmitted light is orange. Captain Abney's films incline to blue; they transmit the green rays, and he contends that his films contain a finer silver bromide than mine do, and that, consequently, they are more sensitive. My emulsions, however, are more easily worked, density being obtained with the alkaline and the hydrosulphite of soda developers, the latter being used as I shall direct. Good results are obtained by mixing the two kinds of emulsion together.

If the albumen should act by causing a fine silver bromide, I find it difficult to account for the thinness of image which Captain Abney's own preparation gives, for fine silver bromide should give a dense image. It seems to me that there must be some other difference between the two kinds than that of the relative fineness of the silver bromide. I am not able to speak positively as to the characteristics of these two forms of emulsion; but Captain Abney, who has tried my emulsion, assures me that my results are entirely different to those he obtains. When making this emulsion, I sometimes find that the silver bromide is formed in large clots, which emulsify shortly after the addition of the excess of silver nitrate. This effect is usual when iodide is present in the emulsion; but with plain bromide it is new to me.

It is at the washing stage that one is liable to fail. Widely different have been the methods recommended—from precipitating the emulsion in water to adding glycerine and allowing to set thoroughly. The process which has gained the prize of the Photographic Society of France includes the former method, though certainly the pyroxyline is precipitated *before* using it in the emulsion. There is no doubt that the quality of pyroxyline has much to do with the result, some samples bearing a treatment which would ruin others. Before the days of washed emulsion, I made several experiments with precipitated emulsion, but the method did not answer well enough for practical use. Even now, when adding glycerine, and allowing to set quite firmly—I may almost say "hard"—I have prepared emulsions which gave films liable to split in all directions when dry. The loss during washing may be about three per cent. It is best to add some gum-ammoniacum solution to such emulsions, and to keep them for a week or two, when they will probably work more satisfactorily.

Though I have experimented a great deal with gelatine emulsions, I must own that I do not like them so well as collodion. I do not think that they are so manageable in any respect as collodion emulsion, and there is much uncertainty connected with their keeping, and with drying the plates. Gelatine has the advantage over collodion in that the ether fumes are absent, and the rapidity is generally greater; but in every other respect collodion is more reliable.

I have experimented considerably with alcoholic gelatine emulsions, but without much success, finding that the bromide is precipitated when over (say) fifty per cent. of alcohol is added to the watery emulsion, and it is difficult to get an even film. The bromide appears to remain suspended best in those solvents in which it has been formed.

I also found that if excess of silver be used it is necessary to add it *after* the addition of the alcohol to the washed emulsion, otherwise it is not possible to use so much alcohol without causing precipitation of the bromide. Again, the addition of silver nitrate to the alcoholised gelatine emulsion causes a precipitation of the bromide, and sometimes of the gelatine as well; the former re-emulsifies on converting the nitrate with a soluble bromide. I may say that these results are nearly instantaneous.

I am much pleased with what I have seen of the new developer—hydrosulphite of soda. With the sample of bisulphite I have used, I find the following method successful with the plates I prepare by Captain Abney's formula:—

Make a stock solution of—

Bisulphite of soda	1 ounce
Sulphite of soda	80 grains
Water	4 ounces.

Pour some of this solution into a bottle of granulated zinc; in about half an hour decant into another bottle, rinsing out the zinc several times with water, which, of course, throw away. To moisten the plate, I use a saturated solution of hyposulphite of soda in alcohol sp. gr. .823, with ten grains of tannia added per ounce; the plate is then rinsed, and sufficient of the hydrosulphite solution, with four grains per ounce of pyrogallie acid added, is flowed over the plate. The development is slow, no image appearing for two or three minutes, so that a developing dish is useful. I find the sulphite of soda a great advantage; if left out, only the high lights take on sufficient density.

This developer gives a good range of half tone, and does not clog up the secondary lights, as is so commonly the case with the alkaline developer, if printing density is sought by its use.

I may say that the developer may be used alkaline with ammonia, in which case the density is obtained without the sulphite of soda, but the peculiar character of the image is easily destroyed.

The developer appears to act in the ratio, or nearly so, of the actinic effect, and I have no doubt will be particularly suitable for cloud negatives.

I will now conclude this somewhat lengthy paper with the hope that I have not quite exhausted the patience of my hearers. I have had much pleasure in introducing this subject, and I now leave you to pick as many holes as you possibly can in the theoretical matter in the first portion of this paper.

PHOTO-STEREOTYPING (PHOTO-ENGRAVING).

A SUBSTITUTE FOR WOOD ENGRAVING.

BY DR. ADOLPH OTT.*

FOR some time past an invention has elicited great interest among photographers, artists, and publishers, by which it is possible to produce a relief plate in metal of prints and

* Continued from page 292.

* A paper read April 26th, 1877, before the Polytechnic Association of New York.

engravings in as many hours as it would occupy the most skilful wood engraver days and weeks. Like many other wonderful discoveries of modern times, this new invention is an offspring of the "black art," photography, and if it will not completely replace the art of Albrecht Durer, it certainly will prove an inestimable boon wherever quick and accurate reproductions of illustrations of any kind are wanted. It is entirely independent of the wood engraver, which is in so far of advantage, as he often fails to give a facsimile of a drawing, while the new process, in being dependent only on chemical and physical laws, is bound to give a perfect copy of any picture or sketch that may be desired; and, although manual labour is not entirely dispensed with, it is reduced to a minimum, being confined to the mere operation of "finishing," viz., to the deepening of wider spaces and the touching up of any portions which may not have come out sufficiently perfect. Or, in other words, the tool of the engraver has become a mere auxiliary instrument, while on the other hand an infinitely greater amount of work can be executed in the same time.

The first impulse to this important invention was given by a seemingly insignificant observation made in 1839 by the Englishman, Mungo Ponton. This investigator discovered that paper which had been soaked in a solution of a chromic salt and dried was rendered sensitive to light, viz., that light coloured it. If an object is placed on paper thus prepared, the parts exposed to light soon assume an orange tint, while the covered parts retain the original colour. On washing with water a white image on orange ground is obtained; that is, the parts exposed to light remain insoluble, while the others are being removed. Mr. Becquerel, the celebrated French physicist, shortly afterwards investigated the action of chromic salts on organic substances under the influence of light, and arrived at the conclusion that the colouration and insolubility were due to the reaction which took place between the chromic salt and the gelatine (sizing matter) in the paper, as in using unsized paper no effect could be produced.

Fox Talbot, in 1852, based on this discovery a method of photo-engraving, or a heliographic process. On a steel plate he spread in the dark a mixture of chromic salt and gelatine, allowed it to dry, and exposed it under a positive cliché to the sun's rays. Now as to the question what took place, we may state that below all those parts through which the light could pass freely the gelatine was rendered insoluble, while under the opaque lines it remained soluble. Such a plate, on being immersed in water rendered a true facsimile of the drawing in the layer of gelatine, the metal being laid bare and forming the ground. It is evident that, by pouring an acid liquid on the plate, the parts laid bare would be bitten in, thus giving an exact copy of the photograph, from which prints may be struck off as if the drawing had been engraved by the artist himself.

Mr. Pretsch, an Austrian, did not rest content at this point. His idea was to produce a relief plate, not a steel engraving, but a substitute for woodcuts, to be set up with type in the printing press. He could not have failed to notice that a sensitized gelatine film, on being treated with water, swells slightly in the parts on which the light has not acted, while it remained unaltered in this respect in the parts affected by the light. This is simply owing to the fact that gelatine will retain its property to absorb water where the light could not act, while it will be deprived of it wherever it has become insoluble. Here, then, we have a substance of which the reliefs and depressions correspond to the lights and shades of the photograph. From this Pretsch took an electrolyte in copper, which represented the image in intaglio when a positive cliché had been employed, and in relief if the sensitized film had been exposed with a negative. However simple this process appears in theory, the difficulty is in practice. The gelatine film is likely to swell still more in the electro-metallic bath (a copper solution), losing its form, &c.; in fact, in spite of all the ingenious devices, the process failed to produce commercial results.

It may be that the great number of artists who are at the disposition of publishers and illustrated journals in the Old World, as well as the prejudices which this innovation met, have also been among the causes that prevented the Austrian inventor improving on his method. But, supposing even the practical difficulties could then have been removed, it is yet doubtful whether an invention of that kind would have found the necessary encouragement on the other side of the Atlantic. To a keen observer it would seem that the United States offered a more proper field, for that is pre-eminently the land of periodicals, illustrated literature, and reprinting. The commercial world also takes advantage of illustrated catalogues and price lists in a much greater degree, and we see the large firms actually overbid themselves with publications of this kind. No doubt such were the considerations that presented themselves to the gentlemen of the "Photo-Engraving Company" (Mr. John C. Moss), and the "Photo-Plate Engraving Company" (Mr. J. Oesterreicher), the latter of whom is a pupil and countryman of Pretsch, and led them to improve the said invention, and to try with it their fortunes here. They have both solved the problem, and it is not exaggerated if we say that they have thus formed a connecting link between the most important invention of ancient times, the art of Guttenberg, with one of the most interesting inventions of modern times, photography. *(To be continued.)*

GERMAN CORRESPONDENCE.

CARBON PRINT IMPROVEMENTS—MACHINE FOR CLEANING PLATES—SUBSTITUTE FOR SUNLIGHT—ELECTRIC LIGHT—SIMPLE METHOD OF ENLARGEMENT—RESULT OF THE TRANSIT OF VENUS OBSERVATIONS—A NEW INVENTION.

BY DR. VOGEL.

THE carbon process still claims the most lively attention of photographers. But the number of those making in reality carbon prints for the public is, indeed, a very limited one, for the difficulties of the process do not encourage a person to join this small number, and there is a want of operators who understand the process. There is, however, much in favour of the carbon process. It produces fine glass pictures in a more simple manner than collodion-chloride of silver; it permits the reproduction of negatives; it delivers durable pictures, and this point is of importance for some purposes, although with some pictures we should not like a too long extent of durability. Every photographer, even if he has not the intention of giving up the silver print, is obliged to take notice of the carbon print, a circumstance rendered more difficult by certain patents. It is certain that some remaining difficulties will be overcome as soon as more photographers make use of the process. One of the greatest faults of the process, which more especially troubled American photographers, was the difficulty of sensitizing and drying the paper in warm summer weather, for often the gelatine, loosened in the chrome-bath or the carbon coating, runs down while drying, and very often the time of drying was such a long one that the coating was decomposed and spoiled. These adverse circumstances can now be prevented by applying alcohol. Boivin proposed at first to add alcohol to the chrome-bath. I have tried it, and succeeded very well. I took

Water...	75 c.c.
Alcohol	25 c.c.
Bichromate of potassium	3 grammes

This bath loosens the gelatine much less than the pure water bath, and thereby a great difficulty is considerably reduced. Besides, the glycerine contained in the paper is less dissolved, and the paper remains more pliant. Boivin asserts that paper sensitized in an alcohol bath dries quicker; and, indeed, it requires only three-quarters of the time that paper prepared in a water chrome-bath does. We can shorten the time of drying by putting the paper after sensitizing in strong alcohol for about five minutes.

Then it will be dry in one hour. This method permits working as quick with carbon tissue as with albumen paper. I sensitize in the morning at nine o'clock, and at four o'clock in the afternoon I have finished some pictures. Although the drying of the carbon tissue takes a little longer time, the time of copying is only one-third that of the silver-printing process; and even carbon prints with double transfer can be ready just as soon as silver prints, which, on account of a most careful washing, have to remain in the water over night.

I must mention a new step forward in the process of cleaning plates. The photographic chemist, Grüne, at Berlin, is cleaning his plates by a machine, which consists of a wheel, on which is fastened a kind of brush all round, and beneath it the plates are moved along by a pusher. The wheel is turned by hand, and the plates, before putting in, are daubed with a dough of infusory dust and water. This infusory earth is found abundantly in the Lüneburg Woods, and forms a porous and very fine and soft silicious earth, which readily absorbs liquid stuffs. In this manner we succeed, indeed, in cleaning plates which otherwise cannot be cleaned.

The spring has brought us so far only storm and cloudy weather instead of sunshine. It is a pity that the surplus of sunshine in America cannot be filled in barrels and sent to us; we would pay a good price for it. We are hunting yet for some substitute for sunlight; inflammable gas, magnesium light, electric light, &c., are applied for preparing enlargements. Recently the greatest attention has been directed to the electric light, since Dr. Siemens, the renowned "electrician," has invented a new magneto-electric machine, which, kept in motion by an engine of four-horse power, produces an excellent light. Such a machine is in use already in the atelier of Mr. Winter, at Prague. I had occasion to test this light photometrically, and have found that it can completely copy, without reflector, a carbon print in seven minutes, at a distance of nine inches, which shows that its effect is the same as the burning of one-third gramme of magnesium wire. The price of such a machine is about \$1,000, and, therefore, the photographers, in order to save this expense, are searching for a cheaper method of manufacturing enlargements without sunlight. Mr. Liebmann, of this city, a young and skilful photographer, operates most successfully in manufacturing enlargements by means of collodion without a camera. He has a small room right under the roof of the house. Through the ceiling of the same he made an opening, in which he placed horizontally the negative to be enlarged. Vertically beneath it he has fixed a portrait objective, which throws an enlarged picture of the negative on a table standing under the objective. On the table he puts the collodionized and sensitized plate. Camera, cassette, &c., are not necessary, for the diffused light of the sky is sufficient for enlargements. The plate can be sensitized and developed in the same room, and the whole concern is a very convenient one. By this process he receives, of course, at first a positive; but Mr. Liebmann prepares from this a negative with little trouble; that is, he copies from it a carbon tissue in a printing-frame, which he transfers on glass. In this manner he receives a negative which is to be put two minutes in a solution of one part permanganate of potash in five hundred parts of water. By this it is strengthened, and delivers excellent copies on albumen paper, which can hardly be distinguished from pictures directly taken.

Three years have elapsed since the observation of the transit of Venus, and we have heard but little about the result, and what we hear is not good news. The measurement of the French Venus plates has shown no sufficient results, though the preparations had been most carefully made. About the results of the English, American, German, and Russian expeditions we hear nothing yet, but it would be gratifying if they could make favourable reports.

The German Reichstag is deliberating now about a

patent law which will be similar to the American. When that is published we shall be overwhelmed by photographic patents. A new invention is already advertised in the papers, which makes a great sensation; it is called "Poykylo-photography." What that means I do not know: certainly the name is something new, and, of course, qualified to impose upon the public who understand nothing about the affair. The pictures are nothing else but photographs made transparent in some way, and then coloured on the back. The latter is done very skilfully, which produces the effect of the pictures, not the process itself, which in similar manner was executed already by Braun at Dornach, Wunder at Hanover, and others. My friend Priimm, the Vice-President of our Society, went over to Dresden, and has seen the pictures. He had also the honour to become acquainted with the inventor, the poykylo-photographer, Mr. Schuhmacher, and found out the sum which he is asking for his American patent, namely, \$80,000.—*Philadelphia Photographer.*

SHOWING PROOFS A NEW WAY.

BY FRANK L. STUBER.

SOME discussion has recently been printed in our spirited contemporary, the *St. Louis Practical Photographer*, on showing proofs, and Mr. Stuber sends the following:—

"Having read your very interesting article in the *St. Louis Practical Photographer*, on the abuse of the showing proof system, I thought I would give your readers a little novelty in that way which I am practising in my gallery at the present time. I find the system takes, and gives general satisfaction. After studying the matter over some time, and experimenting, I hit upon the following plan, by which we can get rid of so many sittings. I have succeeded very well, at least it works splendidly in my gallery. I make my negatives same as usual, four and a quarter by six and a half plates (for card photographs) that size. I am only working at present in this way:—When the negative is developed and fixed, set it on a piece of blotting paper for a few moments to drain, at the same time have a sensitized quarter plate in a small dish or bath-holder; now lay the negative on a table, put two strips of thin cardboard on each side, and lay the sensitized plate on the top, film facing; next, I have a small window in my dark room, in which place a con, which projects outside. At the outer end have a small hole or diaphragm, about one-fourth or one-half inch opening, covered with mineral, tissue-paper, or ground glass. On the inside I have fastened a plate-holder, into which place the two plates, which are held there with a spring. I now pull the slide and expose through the negative for a short time, then develop and wash. I now have a transparency which is far superior to a paper proof, as a general thing. Do not fix the transparency, as it shows to better advantage, and the work is done quicker. Now take it out and lay it on a retouching frame, and cover it with an oval, or any shape matt, then invite the sitter to examine it. I now have the advantage of listening to the criticism, and can correct wherever I see that I can improve the negative by retouching or printing. The great advantage is, that the operator will be more careful in making his sittings, so that he will not have to make a re-sitting. When the transparency is satisfactory, the negative can be varnished, and immediately handed to the retoucher, thereby saving a great deal of time, and the work will be finished so much sooner. At first sight you might think that the sensitizing will cost more than to make a paper proof; but I say not. Now, if you make a paper proof, your negative has to be varnished, the proof printed, turned, &c. The customer takes the proof home, and it is compared with a finished photograph, criticised by those who do not understand anything about the work, or how it will look when finished. They will say, "You had better try again, and then we will take our choice." And

nine times out of ten they will take from the first proof. If the sitter is to be retaken, the operator will very often have to work according to the customers' ideas, thereby making many failures, for every operator should understand best how to produce his work satisfactorily.

"Further experiments show that the positive will be much clearer if the negative is not drained, but exposed immediately after it is washed."

The editor of the *Practical Photographer* says:—

While on the proof business, we will give you more proof that the whole system is a nuisance. We would call attention to an extract from a letter we have lately received from J. W. Bankes, of Little Rock, Ark. Mr. B. ranks high in our profession, being a number one artist; has a fine gallery, and the best class of customers:—

Dear Fitz,—I was glad to notice in your January number an article condemning the showing of proofs. It is high time photographers were taking some decided stand against so degrading a practice. I never do it in my business, and when asked to do so, always peremptorily refuse. I take all possible pains with the sittings, but when I have done the best I can, and think the work good enough to send out, I expect to be paid for my labour. My patrons generally understand this, and hence I have very little trouble on that score.

Occasionally, some unreasonable and hard-to-please individual will attempt the "bulldozing" process, by refusing to sit unless he can see proofs; in such cases I let him go, and consider myself well rid of a troublesome customer.

A lady (?) applied to me for a sitting a few days ago, and stated that she had sat *ten* times at some other gallery, and they had made her proofs, but she would not take any of them. I replied—"Madam, the best thing you can do is to go back to the other gallery, and give them an order; they are surely entitled to some remuneration."

Another lady entered my studio with a child. "Do you make proofs?" "No, madam," was my reply. Her response was the usual one: "They make them at other galleries." The January number of your journal above referred to was lying near, so I turned to the article on proofs, and said: "Please read that, madam." She seemed to read it carefully through, and then said: "I believe he is right." She was much pleased with her child's pictures.

I think photographers who desire to introduce such reforms would find it to their advantage to show such articles to their patrons now and then. It seems to convince them that you are not alone in the position you have taken. And whenever they begin to suspect that there is a general movement in that direction, the battle is more than half won.

If photographers would enjoy the respect of the community in which they live, they must begin by respecting themselves.—Yours very truly, J. W. BANKES.

NEWTON'S SAL-SODA* DEVELOPER AND THE LIVERPOOL DRY PLATES.

A CORRESPONDENT of the *Photographic Times* writes as follows:—

This developer, recommended by Mr. H. J. Newton, President of the New York Photographic Association, has given me better results than any other I have ever employed in the treatment of emulsion wet or dry plates. I have found it especially valuable for what is known as an extra-sensitive dry plate, because it supplies the much-needed intensity. All who are at all familiar with the working of emulsion wet or dry plates are aware that just in proportion to their sensitiveness they develop weak, almost invisible, and quite unsatisfactory; that to

secure a good printing density dry plates must be so made up as to require an exposure four or five times longer than wet bath plates. But this sal-soda developer gives the requisite intensity to the most rapid dry plates.

A year and a half since I imported twelve dozen of the Liverpool extra-sensitive dry plates. They greatly disappointed me. They were very rapid, but the image, developed according to the directions sent out by the Liverpool Company, was painfully weak and unsatisfactory. After repeated trials I laid the plates aside as about worthless, thinking they had perhaps been damaged by dampness in their transit across the Atlantic. After the lapse of a year I again tried them, and notwithstanding the uncommon heat and dampness of last summer, I found them as sensitive, or perhaps more sensitive than at first, but still as weak as ever under the ordinary alkaline pyro developer. I then tried upon them Newton's sal-soda developer, and, to my great surprise as well as delight, the image came out clear, strong, and round. And this developer I continue to use, not only on the Liverpool, but other emulsion wet and dry plates. The following is the formula:—

No. 1.—Water	16 ounces
Sal-soda	2 "
Bromide of ammonium ...	40 grains.
No. 2.—Aqueous solution of pyro (say)	20 grains
Water... ..	1 ounce.

For use, take in a wide-mouthed vial sufficient of No. 1 for the plate, mix with it (when the plate is ready) of No. 2 (say twenty drops for quarter plate), flow on and off till the plate is fully developed.

The energy of the developer can be greatly increased by adding, before the pyro is dropped in, three to twelve drops (according to size of the plate) of the following ammonia solution:—

Water	1 ounce
Ammonia concentrated... ..	1 "
Bromide of ammonium... ..	20 grains.

The advantages of this developer are:—

1. It confers, as already stated, the requisite intensity upon rapid dry plates.
2. While possessing all those good qualities which especially belong to alkaline development, it seems also to possess the additional advantages of the iron developer; for instance, the continuous strengthening of image which distinguishes iron from alkaline pyro development.
3. It admits of a shortened exposure, and is readily adapted to a longer.
4. It is economical, as well as requiring little labour in its preparation.

This developer I regard as a real boon, and worthy of its originator, who, though not a professional photographer, is a gentleman whose scientific research and freedom from those business cares which wealth confers have given him such opportunities of large and varied experiments in photography that any new results published by him are justly regarded as valuable.

Too WHITE.—The story of the negro girl's exultation at being assured by Story, the sculptor (in Italy), that in the marble bust he was to take of her she would really look *white*, reminds me of a case with a quite different result. A finely dressed coloured woman once came into my studio to sit for her photograph. She was dark, and her features of the true type, but her whole appearance rather interesting withal; so I took pains to produce a negative which would yield a face as light as possible, and the resulting photograph was almost as good as that of a white person. I anticipated no little delight when she would see the proof; but think of my surprise when she stared "a long stare" at it, and then exclaimed: "Oh, I don't like that! I ain't as pale as that!" Persuasion was out of place there; she wouldn't have it.—*St. Louis Practical Photographer.*

* Sal-soda is an old-fashioned term much used in America to indicate ordinary carbonate of soda, or washing soda, as it is at times called.

PROTECTION OF GLASS STUDIOS FROM THE WEATHER.

At the last meeting of the Vienna Photographic Society an interesting discussion took place on the subject of protecting glass studios from the ravages of storm and wind. In this country, fortunately, we are not frequently troubled with the storms or tornadoes that are at times felt upon the Continent. At the same time our readers will, no doubt, be glad to hear of the many suggestions which our Austrian brethren have made with a view of relieving photographers from the loss which they occasionally suffer from the causes above mentioned.

M. O. Kramer, a well-known Vienna dealer, suggested the formation of an insurance company against the ravages done by hail, which, it seems, is what our friends hold most in dread. There was, according to M. Kramer, a plate glass insurance company, but the premiums charged were something like ten to twenty per cent., and would, therefore, form a considerable charge upon the income of a photographer. In M. Kramer's opinion the employment of hardened glass would meet the case, which, he said, could now be obtained at a price not more than twenty-five per cent. above that charged for ordinary glass. M. Fritz Luckhardt remarked upon the employment of wire screens by some photographers, a proceeding which robbed them of a good deal of light. So far as hard glass was concerned, he considered it more suited for printing frames than any other purpose, and stated that the firm of Lotze, in Pilsen, which occupied itself with the preparation of such material, declined to undertake an order unless it amounted to fifty plates, the glass being sold for fifty kreuzers (about tenpence) for a sheet measuring twenty-one by twenty-seven centimetres. Baron Schwaz-Seuborn remarked that in France, and particularly in Paris, where hail storms were very prolific, straw coverings were in use for the glass roofs; he believed also that the employment of hardened glass would diminish the risk of damage, for M. De la Bastie, the inventor of the process, was an amateur gardener, and had been led to make his experiments with glass by the losses he had experienced from the weather. The glass was now rendered hard, not by immersing it, when in a state of fusion almost, in a mixture of paraffin and wax, as was formerly the case, but by transferring to a bath containing certain salts in solution. A factory of hardened glass had been established between Vienna and Dornbach under the superintendence of M. Chapelle. M. Jaffé was

of opinion that it was not the hail so much as pressure from snow which wrought such destruction in winter time, and suggested a stouter framework for studios; but the objection was made to this that the light would be thereby diminished. In the end the President was inclined to favour the use of hardened glass, and called attention to the manner of producing it by Siemens, of Dresden, who pressed the glass plates between heated cakes of clay.

TWO NEW LENSES.

At the last meeting of the French Photographic Society two lenses were brought forward, the one termed the Eury-scope being the production of MM. Voigtlander and Sons, of Vienna, and the other the work of M. Prazmowski.

In regard to the former, M. Carotte offered the following remarks.

The construction of this lens is based upon calculations made by Dr. Sommer, Professor of Mathematics and Director of the Brunswick Polytechnic School. It is composed of two achromatic and symmetrical lenses, in the centre of which the diaphragm is placed; the instrument is perfectly aplanatic, working with an open aperture.

Nevertheless, a certain degree of curvature being inevitable, if absolute sharpness is required to the edges they may be secured by the employment of a diaphragm of greater or less dimensions. The lens is especially suited for views, as it gives perspective with entire truth; it also permits the securing of reproductions, monuments, interiors, and groups, both in the studio and out of doors.

The instrument gives straight lines without deformity; its chemical focus coincides with its visual focus, and there is an absence of flare. What especially distinguishes the lens, however, is its luminous capacity. Another important advantage is that it embraces an angle of sixty-five to eighty degrees, according to the nature of the diaphragm employed.

In regard to the Prazmowski lens, the constructor of it gave the following particulars. The lens I have the honour to submit to the Society gives results similar to those indicated by M. Carotte, and I have brought it forward to-day, so that there may be no pretence that it is any imitation. It is based on the principle of former lenses used exclusively for inanimate objects. By making a suitable choice of flint and crown glass, the lenses which compose my instrument have rays with a curve much more extensive than those of my panoramic lenses. The feeble curves permit the instrument-maker to give his lenses diameters relatively large, and so let them admit enough light to take groups and even portraits.

The distance between the lenses forming this instrument is much larger than in my panoramic lenses, a circumstance which renders the field more limited.

The principles which guide me in the construction of lenses—principles which permit, according to the nature of the material employed, to give either the wide-angle necessary for panoramas, or the limited angle for groups and portraits—are as follows:—

There enter into the composition of the photographic lens two vitreous substances of unequal optical power. The less difference there is between these powers the more the lenses take the form of a globe; and at the same time, to have a perfect flat field, the lenses must be approached to one another. The rectitude of the lines is assured by perfect symmetry. As the difference of the indices of refraction and dispersion augments, the globe becomes flattened, the curves diminish, but the distance between the globes augments. Given two substances whose optical nature has been well studied, a more or less simple calculation will determine all the elements of the lens—the curvature of the rays, the thickness, the most suitable dimensions of the lenses, and their distance one from another. The quantities are all

perfectly determined, and there is only one solution to the problem possible.

It is by uniting together in pairs the different kinds of glass that I have been able to construct the different lenses which I have had the honour to submit to the Society. The one I have with me to-day is but barely finished, and I exhibit it only in order to put in a claim as its originator.

THE INTENSIFICATION OF CARBON PRINTS.

In the *Photographische Correspondenz* appears an exhaustive article on the subject of intensifying pigment images for the production of negatives and other purposes. It is from the pen of Herr Karl von Stefanowski, and from it we have taken the following as being of particular interest to our readers.

Permanganate Intensifying.—As I have already mentioned, permanganate of potash is now universally employed for intensifying carbon prints. This compound renders them of an olive green, and therefore makes the images peculiarly suitable for photo-lithographic work.

If the permanganate-treated carbon print is covered with pyrogallie acid, it rapidly becomes of a sepia-brown, and acquires more vigour.

Gallic acid and tannic acid colour the pigment picture almost of a pure black; the depth of the tone depends upon the amount of these re-agents in the solutions.

Treatment with pyrogallie, gallic, and tannic acid renders the images suitable for diapositive. Sulphide of potassium and ammonium decolorize the above intensifications, and may, therefore, if need be, be employed for clearing up pigment pictures that have been treated.

A remarkable behaviour is apparent in the pigment image by the combination of the brown oxide of manganese and extract of logwood. If a permanganate image is brought into a solution of logwood, the colour varies of all shades between blue and rose-violet according to the strength of the solutions, and their temperature, and the time of the sojourn of the image in the bath. A lengthened immersion in the logwood solution darkens the image altogether, and robs it of its high-lights. This method of proceeding, however, notwithstanding that it is an energetic one, cannot be recommended either for negatives or diapositives, as it requires to be thoroughly studied until the operator is in a position to secure with certainty the desired result. The film often becomes insoluble by the treatment.

Iron Intensifying.—Laurent gave a bluish-black tone to his carbon prints by treating them with an old iron developer and gallic acid solution. This plan Mouckhoven has recently improved, the latter proceeding as follows:—The pigment image is brought successively into three solutions, and washed between every stage. The first solution consists of forty grammes of sulphate of iron in one litre of water; the second of twenty grammes of pure carbonate of soda in one litre of water; and the third of ten grammes of gallic acid in one litre of water. The image remains in the first solution five minutes, in the second ten minutes, and in the last until it has assumed the desired violet tone.

According to my experience any iron solution may be employed for intensifying the pigment image, the presence of oxide of iron or of salts of the oxide having but an influence upon the colour that results. If, therefore, it is desired to make use of an iron intensifier, any iron salt that may be to hand can be employed, whether the same happens to be an iron developer, sulphate of iron, or what not. Chloride of iron behaves in the same way as oxide of iron as an intensifier. The action of the iron is very rapid when a concentrated solution is made use of. If the intensified result is to be used as a diapositive, then of course a tint is chosen which seems to the operator the most agreeable.

Pyrogallie acid employed upon an iron intensified image renders the same of an intense brownish yellow (warm sepia).

Gallic acid and tannic acid upon an iron intensified image gives, according to the nature of the iron salt employed, a series of violet and deep bluish-brown tones.

Sulphide of potassium and ammonium yield a deep black colour with green reflection. This intensified film is a very opaque one.

Alkaline carbonates colour the iron image reddish-brown. This plan of intensifying must be carried out with care, and must not last too long, since the alkalies have a tendency to render the film reticulated, and to decompose the gelatine.

The iron image may in the same way be coloured by permanganate of potash. If the image is not sufficiently washed, it assumes a surface of metallic lustre, which does not injure the picture regarded as a transparency. If the picture is further treated with gallic or tannic acid or pyrogallie acid, it assumes a dark or blackish-brown tone.

A deep blue tone may be imparted to the iron picture by the action of red prussiate of potash, and a deep green tint by a mixture of yellow prussiate of potash and bichromate salts.

To diminish the action of the iron and any tendency to fog, and to impart more contrast to the negative, a clearing liquid may be made use of consisting of a weak solution of oxalic acid, and afterwards of citric acid.

Lead Intensifying.—If a carbon print is brought into a four per cent. solution of nitrate of lead, and then treated with liver of sulphur or sulphide of ammonium, it will rapidly assume a dark reddish-brown colour.

Bichromate of potash and bichromate of ammonia upon a lead intensified image produce chrome yellow in the picture, and colour it, by reason of the pigment it contains, of a greenish tint.

Alkaline carbonates colour a lead pigment image white, and the opacity of the latter may be increased by treatment with sulphite of potassium or sulphide of ammonium, whereby the picture is made to assume a brownish tint.

If the lead image is put into a solution of yellow prussiate of potash, and then immersed in chloride of iron, it is coloured by the first liquid white, and by the second dark green.

If the lead treated film is allowed to soak in a mixture of nitrate of lead or red prussiate of potash, it is afterwards put into an iron solution, the picture assumes a deep colour.

Silver Intensifying.—A carbon image soaked in gallic acid, and then dipped into a two per cent. solution, is made to assume an agreeable brownish-black tone.

Pyrogallie acid and nitrate of silver allowed to work upon the image furnish warm purple-black pictures.

Bichromate of potash or bichromate of ammonia and nitrate of silver make the image of a brick red.

Red prussiate of potash and nitrate of silver produce warm black prints.

Sulphide of potassium or ammonium and nitrate of silver furnish an intense black with purple tone.

A mixture of permanganate of potash and nitrate of silver yield warm purple-black pictures.

Chloride of iron, then nitrate of silver, and afterwards gallic acid, produce black images.

Chloride of iron, followed by nitrate of silver, and further with pyrogallie acid, gives warm purple black tones.

Pyrogallie acid followed by silver nitrate, and then liver of sulphur or sulphide of ammonium, yields an intense black image of a purple tone.

Chloride of nickel followed by silver nitrate and pyrogallie acid gives a warm purple black colour.

(To be continued.)

A METHOD OF OBTAINING SOFT PRINTS FROM HARD NEGATIVES.

BY R. E. COURTENAY.

THE negative should be varnished, and a piece of the auto-type tissue of the purple tint floated on the same in the bichromate bath; the excess of solution is displaced in the usual way for transparencies on glass, and dried; when dry, expose from ten seconds to forty, according to light and requirements; develop in the usual way with warm water. The proofs from a negative so treated, compared with one before treatment, will show the value of the process. You see, it is a carbon positive on a negative.

If the whole of the shadows are not required to be covered as above, retouching the negative can be accomplished as follows: pure gelatine and white sugar mixed with a little bichromate of potash, and the negative coated with the solution and dried in the dark, is exposed as above for a few seconds, and developed; treat the parts required to be softer than others with gallic acid by means of a sable brush, and then with sulphate of iron; many other solutions will do as well as those mentioned.

RESTORATION OF PRINT BATHS.

BY A. STOCK.*

TILL now it has been customary to treat silver baths, whether they have been employed for the dipping of plates or sensitizing of paper, in precisely the same way when defective or out of order, notwithstanding the fact that the print bath becomes contaminated with quite a different series of organic compounds and impurities. This should not be, for the latter requires, as a matter of course, special treatment, although, strange to say, no manual gives any definite information on the subject. The ordinary impurities that enter the print bath are: gelatine or size, superfluous acid, and combination of the latter with the chloride salts employed in the preparation of the paper. The precipitation of the gelatine matter, as of the organic compounds, is brought about by the following means:—

1. The silver bath is treated with alum solution of 1 : 10 strength (ordinary alum dissolved in hot distilled water) until small crystals are seen to form, when the liquid is filtered. These crystals are silver aluminate, which are dissolved again in hot distilled water, and added to the silver bath again; a portion remains dissolved, while the rest again separates. This silver-aluminate may be employed, therefore, again and again.

2. By adding and filtering off again burnt alum or hydrated clay, for, as is well known, the oxy-hydrate of aluminium possesses a considerable tendency to combine with organic substances, and precipitate the same when in solution. As the hydrated clay exerts the same action against colour, it is far preferable to permanganate of potash when any discolouring of the bath takes place.

If the print bath is acidified pretty strongly with acetic acid, and then kaolin added until the smell of acetic acid has disappeared, and the whole filtered, then the sizing material is also completely coagulated by the acetate of aluminium which has been produced.

There remain still the different acids and their salts to neutralise and decompose. To do this, carbonate or bicarbonate of soda have hitherto been recommended to be employed. Now, although both those compounds, and especially the latter, are excellent agents for neutralising the silver bath, I have never found the result to be a marked improvement in the bath.

On the other hand, we possess in caustic potash and soda two excellent means for neutralising and decomposing acids and salts present in the print bath. Both are dissolved in ten parts of distilled water. From one of the

two solutions (the first is to be purchased of any chemist) enough is added to bring about a gelatinous precipitate, the liquid being from time to time vigorously shaken. The silver bath now assumes a transparent, milky turbidity, or, if it does not, more caustic potash is added, until the turbidity does not disappear, and litmus paper betrays a neutral reaction. This gelatinous precipitate cannot be filtered off either by means of bibulous paper or cotton wool, as all the pores are very soon plugged, and only moistened linen or flannel can be used for the purpose. The linen or flannel is strained tightly upon a square wood frame, and the liquid poured into the middle; the strainer must not touch at the bottom, but remain free. Neither must it be pressed, as in that case some of the gelatinous precipitate is forced through. It is well to let the filter process go on during the night, and then there is plenty of time for the liquid to run through bright and clear. Those who are not conversant with this method of filtering or straining should be initiated into it by a chemist. After the operation the cloth may be dried, and be employed again.

In adding various substances to the print bath in order to purify it, one need not be nervous about going to work, for there is no harm in being a little out, and the print bath does not require such delicate handling as is the case with the negative bath.

Print baths treated in the manner described will be found to possess all the properties necessary to good working, and to impart to albumenized papers the finest lights and shadows. At the same time, the restoration of a print bath should not be delayed for any length of time, as sometimes happens with the negative bath, but should be treated periodically, especially so far as neutralisation with caustic potash is concerned. If the bath becomes too alkaline, it may easily be rendered neutral again, after straining, by the careful addition, drop by drop, of pure nitric acid.

In the above lines I have desired to indicate the theory involved in the proper restoration of the print bath, and thus to acquaint my friends with the why and wherefore of the reactions.

Dr. Liesegang, in connection with the subject, points out the method employed by Mr. Maxwell Lyte to purify turbid, brown print baths, a method which Dr. Liesegang has somewhat simplified. The following solution is prepared:—

Spring water	...	100 grammes
Phosphate of soda (crystallized)	5	"
Carbonate of soda (crystallized)	20	"

To every litre of brown print bath is added ten grammes of the above solution, the whole being vigorously shaken, and then filtered. The bath runs through the filter perfectly bright and clear. Afterwards, for every ten grammes of the above solution that have been employed, there is added to the print bath one gramme of nitrate of silver. The residue collected upon the filter-paper should not be thrown away, but added to other silver residues to be worked up at a fitting opportunity.

POPULAR MISTAKES OF PORTRAITISTS.

BY H. M. BEELES.*

AN opposition of a few of the many mistakes which the photographic artist is liable, and some of which is probably common to the entire fraternity, may not be out of place; therefore, while I call your attention to these, I beg you will either excuse or expose any error into which I may fall.

When a new-fledged candidate for public favour, whose business in the future is to be the painting of the human

* *Photographisches Archiv.*

* *H. Louis Practical Photographer.*

form divine by aid of sunlight, camera, and retouching pencil, first steps upon the platform and makes his *debut* with a graceful bow he must needs advertise, and that is all right, of course. But the nature of the advertisement is wrong in nine cases out of every ten. It reads something as follows:—*Announcement.* John Smith, Jun., takes pleasure in informing his friends and the public generally that he has just purchased an entire new outfit of the most approved style, and at a great cost; also, that he has learned the art of photography, and is now fully prepared to turn out first-class work every day in the week, &c., &c. N.B.—Satisfaction guaranteed or money refunded!!! Gallery over Snap and Ketchum's dry-good store, Pennygrab, Gold Co., Wn. Ter." I will not assume that John Smith, Jun., made a mistake in choosing a calling, for that only can be proven by after events. I will not assume that his manner of introduction to the public is a mistake, except in one respect, and that is found in the last sentence: "Satisfaction guaranteed or money refunded." Seizing on this proposition, the public is at once made aware that it can impose upon poor John as much as it likes, and then, under the plea of no satisfaction, demand restitution of money, and so he is out of chemicals, rent, time, and, worst of all, has impressed on the mind of the customer that he is an indifferent artist at the most, and one who has no confidence in himself, or else one who intends, under the plea of great fairness, to gull the public.

What would we think of a miller who would advertise thus? It is a common, I think universal custom, for artists to make a negative, and if the first proof is not satisfactory to make another, and again repeat the operation *ad infinitum*, and at last make half a dozen or dozen cards to compensate for all loss of time and chemicals. No other tradesman in the world would for a moment entertain an idea of doing business in this way. I do not blame the public—for this the artist is wholly responsible—but the public take advantage of it. For instance, a lady desires some photographs; she sits; when the proof comes she finds, to her horror, that blue did not take black, or that some ribbon on her hair looks awful. Why, it's so large; just as though the artist had not told her so at the time of sitting, and tried to dissuade her from wearing it. She looks so big or so small, or there is a wrinkle in her dress, or some other fault which she fastidiously conjures up to obtain another sitting, and so John has to sit her again and again, until either his patience or hers is worn out; and, perhaps, John has not got a cent for his trouble, and has overruled one to the opinion, to be publicly expressed, that he is a very poor artist. Suppose every artist should abrogate this rule, and, instead, should charge for negatives and photographs separately, and when a negative satisfactory to the operator is obtained, collect pay for work done; then, if the sitter wishes to have another dress photographed, she can have it by paying for another negative. Suppose that were the rule, there would be no occasion for a Pearl suit, and I venture it as the opinion of your humble servant, that there would not be half the negatives retaken. It is not a matter of any consequence whether the pictures are paid for or not at the time of sitting, but the negatives should be. Many artists are not arbitrary enough in regard to matter of dress, and in accessories as he should use. Often we find a picture in which the accessories are far the most prominent part of the picture, the face being wholly subordinate, and, as one would suppose, the last thing to be looked at.

Artists often confine all experiments to chemical manipulation, and none scarcely to the management of light or background, both of which are fully as great importance; but any experiment to be useful must be intelligently conducted. Very few great improvements have been the result of accident, though some have. Want of harmonious action and fraternal feeling is a great drawback on our financial success, though I am happy to say that in this there is a marked improvement.

HYPO IN THE SILVER BATH.

BY D. O. MUSKER.*

THE following formula for a nitrate bath I discovered by accident, and it happened in this way. While preparing to compound a bath, I had weighed out some silver on the scales which I had been in the habit of using to weigh hyposulphate of soda upon. Having weighed the amount of silver that I intended to use, I proceeded to empty it into the bottle containing the water. Noticing a crystal left on the pan of the scales, I picked it up, and dropped it into the bottle; it had barely left my fingers, when the thought struck me that it was hypo, and not silver. A second's time was sufficient to convert my fears into a certainty, as the crystal left a brown track from the top of the solution to the bottom. There was no retracting from what I had done, so taking up the bottle, I gave the contents a thorough shaking, and after directing a few choice epithets to myself, for being so careless, I set the solution away for future precipitation, and proceeded to make a new bath, in which, you may be sure, I did not put any hypo.

Some months after, upon getting this conglomerate around to precipitate, preparatory to sending to a refiner, and having a good deal of the curious in my make up, of course I could not proceed with the precipitation until I had tried a plate to just see what the effect would be, you know; and judge of my surprise, when upon developing, not a hopeless fog, as I had expected, but an unusually clear chemical effect, was presented. I went directly and picked out a piece of soda, as near the size of the piece that I had accidentally used as I could remember, and made a memorandum of the weight. This was the best and longest working bath that I had used for a long time. Still I had no confidence in hyposulphate of soda as a good thing to put into a negative bath, and did not try it again for a year or more; but when I did, it was with the same results. Again I dropped it, and again I have just made another hypo-nitrate bath, and find it the same as before. I have never had a bath in this way that has not worked directly and unusually clear.

The formula is—

Nitrate of silver	5 ounces
Hypsulphate of soda	5 grains
Water	60 ounces.

Dimolve the silver and water together; iodine, and try without adding acid. If acid is needed, add one drop, chemically pure, at a time. More soda might be better; some one try.

PHOTOGRAVURE.

BY M. DESPAQUIS †

THE process I am about to describe is one which I have employed for the past five years for making seals, stamps (either wet or dry), and similar impressions, for letter-paper or bill-headings, and the like, a photographic cliché with half tones being a first step in the method.

I make a positive upon glass with a collodion prepared with a pulverulent pyroxyline, and containing a small quantity of castor-oil to give the film the suppleness and toughness which it requires; or I take a positive secured by the albumen process, an image formed by gelatine, I find, tearing when it comes to be worked upon with the graver. I choose a positive with well marked blacks and whites, and not one of a clear grey or of a nearly uniform tint.

With a steel point or graving instrument I draw in the blacks of the image, and in the deeper half-tones some fine lines with definite spaces between, in the same way as a wood engraver proceeds. The point of the instrument renders the glass perfectly bare, for it removes the collodion whenever a line is drawn.

With a pen or very fine brush, and some Indian-ink, or

* St. Louis Practical Photographer.
† Monteur de la Photographie.

any other anti-photogenic colour, I next proceed to put in lines or a very fine stipple upon the whites of the image, and the more delicate half-tones, proceeding, indeed, in the reverse manner to what I did before.

This work can be undertaken by a skilled hand at very little expense, and I am charged very little for it, so that the proceeding is by no means costly. To work more freely I obtain a positive, whole-plate size, and after this has been worked up to my satisfaction, I then secure from it a small negative of the size I desire for the seal, stamp, or what not. From this little negative I produce a positive upon metal (cast steel if it is for a stamp) by the aid of bitumen. By the bitumen process the very delicate half-tones are not retained when the printing has been completed, and you proceed to development by means of the essence with which the unsolarized parts are washed away. There remain, indeed, but the lines or stipple which have been worked up by hand with the pen or brush.

The bitumen image, being thus developed upon the metal, is well washed, and then the etching may be proceeded with. This takes place in the ordinary way with acid, the bare metal portions being attacked, while the others, covered with bitumen, are protected from the action of the mordant. M. Despaquis points out that the process can also be employed with effect in chromo-

RECOVERING OF THE GOLD FROM THE GOLD BATH.

BY DR. SCHLEISER.*

DURING my long experience it happened very often that paper was given to me full of brown powder supposed to contain gold. In most cases there was only a very little gold in it, which would not cover the expense of refining it. I will give some practical hints how photographers can gain the gold residuum in the most profitable manner, and mention at first that the gold precipitated in fine brown powder may be known at once by its lustre when rubbed with steel. When the residuum contains a quantity of gold, it will show this mark of gold lustre; in the other case but a trace of it.

In old gold baths the gold will part itself after long standing completely in metallic shape, and this so much the quicker when at first a metallic precipitate is formed. If we have to do with gold baths which we suppose contain some gold yet, the bath must be weakly acidified with muriatic acid, so that the bath will colour faintly red a piece of blue litmus-paper; and then it is to be mixed while stirring it up with a diluted solution of vitriol of iron, 1:2.

The iron solution reduces the gold and precipitates it metallically as fine red-brown powder. After the precipitate has settled, it is to be washed out in acidified water till all iron is removed.

The precipitates which form in the gold baths before mixing it with iron, by standing for some time, are to be dissolved in one part nitric acid and three parts muriatic acid, and after evaporating the surplus of acid, dissolved in a little water, and treated with the iron solution, as explained above. The gold powder received in this manner can be easily sold.

Correspondence.

PUBLIC CRITICISMS OF PHOTOGRAPHIC MANUFACTURES.

SIR,—I have found more than one person disposed to "chaff" on reading the letter of Commander Turton in your last. I for one am disposed to agree with him, and

* *Photographic Times.*

to complain that there is too much reticence at photographic societies and in the journals in speaking of the quality of photographic articles offered for sale. I must confess, however, that I approach the subject from a somewhat different stand-point to Commander Turton. I am a manufacturer of various photographic commodities, and I feel certain that if the photographic societies and journals would only give me *carte blanche*—or, in rough vernacular, give me "my fling"—I could say some very interesting things on the excellence of my manufactures. Of course Captain Turton will see that what is sauce for the goose should be sauce for the gander; and if purchasers had the full right for complaint which he desires, producers should have a similar right to introduce and praise their goods, instead of being compelled to resort to the sordid practice of paying for advertisements. In the meantime, whilst the latter system prevails, would it not be fair if Captain Turton and gentlemen of his mode of thinking were content to ventilate their grievances in manner similar to that which the manufacturers must employ in making their goods known? If this were so they would be less anxious, I fancy, to publish failures which may be due as much to imperfect manipulation as bad plates.—Yours,

A MANUFACTURER.

ART IN PHOTOGRAPHY.

DEAR SIR,—Professor Green's excellent paper entitled "Can Photography Make Pictures?" which appeared in the NEWS, May 26th, and which from my own experience I can say is by no means too highly coloured, must convince your readers how meagre is the amount of artistic knowledge possessed by photographers generally, and point to the urgent necessity of some systematic course of instruction for young beginners of a much higher character than at present afforded.

Education during the last fifty years has made such rapid progress that totally illiterate persons in the lower ranks of life is now as much the exception as it used to be the rule. Therefore, there can be but little difficulty in obtaining intelligent youths having a fair share of scholastic knowledge, as pupils or apprentices, and it is in these characters only that I should be willing to admit any to share in the secrets and working of a photographic establishment.

It has been from a neglect of such a regulation as this that the profession has become inundated with assistants, whose only stock of knowledge consists of what they may have picked up while serving as errand-boys, and some little practice with a cheap apparatus of their own. I have not had much experience with assistants lately, and hope as a class they are improved; but only a short time back it was rare to find one who could be trusted to make a developer, or any other solution, or even know the names and value of the weights to be employed; neither is this to be wondered at, for what master would care to take any trouble with a boy who might leave him even without a moment's warning, and who was, generally speaking, of a very low grade as to education and manners? I therefore consider that the first step to a better system of initiation must be the institution of a legal term of servitude to be fulfilled by youths either as apprentices or pupils. In this way only can masters expect to be repaid for the trouble and expense of their training.

Some short term of probation is necessary before signing indentures, so that the masters may see a probability that the youth's habits, temper, and inclination, are such as to promise well for the future. Rudimentary works and books of instruction should be placed at the pupil's disposal, which he should be encouraged to study. A great aid to his advancement will be found in the art science classes with which almost every town is now provided, and the master will find it much to his interest to allow the pupil time and opportunity to attend them.

Practical knowledge will of course be gained by the daily

business routine of the establishment. But I must say that in all cases the proficiency of the pupil at the expiration of his term of servitude will mainly depend upon the intelligence and knowledge of the master himself. The pupil must not think that his knowledge is any more than rudimentary, and try to improve it by practice under various masters, and study, not forgetting the photographic journals. Now, the photographic societies might render the greatest service. Each should have its library, lecture-room, laboratory, and studio, superintended by professors, and, as a climax, there should be collegiate examinations and certificates. By such a system we should obtain such a class of men as would make the art of photography worthy of the respect of the world. Literature is every day offering such an abundance of new works that I fear to propose a series of progressive books of instruction, but should be much pleased to see this done by competent persons.

JAMES MARTIN.

5, Clarence Place, Ilfracombe, June 16th.

PS.—I wish to obtain old or modern French or German songs, ballads, poems, legends, or romances. Could any of your readers kindly forward me such, or otherwise assist my purpose.

Proceedings of Societies.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE third out-door meeting of the season was held at Arncliffe on Thursday, the 21st; but in consequence of the somewhat dull appearance of the morning, the attendance was not so large as usual. The party started from the Mound at 9.25, and drove by the old road past Craigmiller Castle and through Dalkeith; and as the clouds had broken up, and the sun made his appearance, everything looked favourable for a good day's work. Most of those present had been frequently at Arncliffe, and missed the familiar landmarks by the way; but the driver assured them that he knew the district perfectly, and was going the shortest road. By-and-bye, however, it was evident that the shortest road was occupying much more time than it ought to have done, and on a council being held the discovery was made that the driver had read Ormiston instead of Arncliffe, and that they were within a short distance of the former place. This mistake, somewhat discouraging at first, soon turned out to be a real advantage, as, being instructed as to a route across the country, they enjoyed a drive through scenes of varied but exquisite beauty, altogether out of the beaten track; and although Arncliffe was reached fully an hour later than was expected, no one regretted the delay. Just as the grounds were reached a sharp thunderstorm came on, accompanied by heavy rain; but under the cathedral-like covering of the celebrated beech avenue the members enjoyed their luncheon without a drop reaching them, although, thanks to Councillor Hay and the Treasurer, the luncheon was not by any means dry. The rain proved but a passing shower, and in a short time the cameras were at work in, perhaps, one of the most beautiful and photographically suitable places within not "a mile," but twenty miles, "o' Edinboro' Town."

In the course of the day the members assembled for the transaction of business, the President taking the chair on the banks of the river. After the usual preliminaries the following gentlemen were admitted ordinary members. Messrs. William and James Bertram, J. Gibson, J. Micheth, and John Heron.

The return journey was commenced at six o'clock, and the party got to Edinburgh between eight and nine, highly pleased with the excursion, although not, in consequence of want of light, very sanguine as to the results of the exposures made.

FRANCE PHOTOGRAPHIC SOCIETY.

A MEETING of the Society was held on the 1st inst., M. DAVANNE in the chair.

A letter was received from the Belgian Microscopical Society inviting an exchange of publications.

M. PERROT DE CHAUMEUX passed in review the foreign journals. He referred to the employment of carbolic acid by M. Friedlein, of Vienna, who advocates the use of this acid whenever gelatine solutions are applied, the only defect of the carbolic acid being to harden the surface of the gelatine a little on drying.

The formula M. Friedlein employs for his bichromate sensitising bath for pigmented tissue is:

Bichromate of potash	30 parts
Water	800 "
Fluid carbolic acid	1 part

Moreover, during summer is added—

Glycerine	1 to 6 parts
-----------	-----	-----	-----	--------------

To obtain fluid carbolic acid, five parts of the crystallised acid are warmed in a water-bath, and then one part of warm water is added.

M. DAVANNE read a communication from Dr. Fayal on Micro-Photography [the tenour of this has already appeared in the PHOTOGRAPHIC NEWS].

M. PERROT DE CHAUMEUX acknowledged the receipt of a pamphlet by M. Chardon, entitled: *Photography by means of dry emulsion prepared with pure bromide of silver*.

The particulars of the competition instituted for improvements in travelling equipments were read.

Also a communication from the Commission entrusted with the competition to be entered into for a substitute for glass, the prize to be delivered for a film which, while not so heavy and fragile as glass, shall lend itself as well to photographic manipulations. The prize in this case is a large silver medal, and the competition is international. Essays already made will be admitted as new inventions, and specimens must be delivered before the 1st of January, 1878. The process to which the prize is awarded must be described in the *Bulletin in extenso*, and will become public property.

M. JARON submitted a numerous collection of photographs, being reproductions from the Stockholm Gallery.

M. ANDRA stated that he was continuing his researches with M. Chardon's collodion, and, in conjunction with M. Rousselon, was attempting the reproduction of pictures by its means. M. Rousselon believed that three times the exposure was necessary. Since the commencement of the experiments M. Andra had prepared several litres of emulsion according to M. Chardon's formula.

The PRESIDENT remarked that the Commission had met a second time to make themselves acquainted with the keeping qualities of the Chardon plates, the results being very satisfactory.

M. CHARDON called attention to one or two errors that had been published regarding his process.

M. QUINAC, of Toulouse, exhibited some prints in greasy ink, which, in regard to delicacy, tint, and half-tone, were not inferior to silver pictures. They had been produced from grained copper plates coated with bichromated gelatine. As many as five hundred examples had been struck off some of the plates.

M. CAZETTE exhibited a new lens by Voigtlander called the Euryscope (see page 306). He asked that a Commission be nominated to examine it.

MM. Balaguy, Franck, Joliet, Martin, and Rousselon were nominated members of the Commission.

M. PRASNOWSKI also exhibited a new lens (see page 306).

M. FRANCK DE VILLECOULLE said it was very desirable that the lenses in question should permit of the taking of group pictures; the aplannatic lenses which he had hitherto examined left much to be desired in this respect.

M. A. MARTIN made some remarks upon the subject of so-called aplannatic lenses.

M. ANGOT read a paper on the application of photography to astronomical purposes.

The proceedings then terminated.

Talk in the Studio.

THE NEW SUMMIT.—Mr. Alderman Notlage (of the London Stereoscopic Company) was, a few days ago, elected one of the Sheriffs of the city of London for the ensuing year.

ALBERTY IN PORTRAITURE.—To make the Albertype available to portrait galleries, it only requires one establishment in each city, or large town, where prints could be made for every gallery within a circuit of several miles, and all could then guarantee imperishable pictures. Fine results can only be obtained by experienced printers, and a regular establishment can produce better work at a reasonable price than could be made by an occasional printer. Prints can be made of any size, being limited only by the size of the press. One of our New York photographers, Mr. Kurtz, has adopted the process

for life-sized heads. They are printed in pure black ink, on the best drawing paper, and then retouched with crayon, in his well known style, the paper has no chemicals in it to wash out, but is left with its original surface, made expressly for drawings. This is a step in advance of solar printing, for there has not yet been a solar print made but that would show the difference in colour of the printing and retouching after being made a short time. This can never occur with the Albertype, as both the ink with which the picture is printed and the crayon are made of the same materials. The public is beginning to see this, and will soon demand a guarantee of absolute permanence.—*St. L. and Practical Photographer.*

COLOURS OF EMULSIONS.—The colour of an emulsion, as a rule, has been supposed to be a test as to its quality and sensitiveness, and it has usually been insisted upon that a film which transmits the orange rays alone, absorbing the green, blue, and violet, is in a fair way to give a good image on development. It must not, however, be forgotten that this test is by no means theoretically certain. The colour which is transmitted through an emulsion film depends on causes which are partially, at least, independent of the light which the sensitive salt can absorb. The transmitted light is dependent to a large extent on the size of the particles formed, whereas that transmitted through a transparent body is probably dependent on the quantities of the ultimate molecules. The difference will be readily understood when we say that it is possible to form an emulsion through which only red rays can pass, and which is formed of matter which, before being divided into small particles, allows every colour of the spectrum to be transmitted. In considering, therefore, the probable effect of the colour of an emulsion, it is necessary to divide the causes of such colour into two classes.—1st. Those which are entirely dependent on the absorption by the emulsified matter itself, 2nd. Those which are due to the scattering of the particles into which such matter is divided.—*Photographic Journal.*

NICKEL-PLATING WITHOUT A BATTERY.—Dr. Kayser has succeeded in coating metals with an alloy resembling German silver, thus giving them a handsome finish, and making the surface more durable and permanent than that of tin or silver. He first melts together one part of copper and five of pure tin—preferably the Australian. The alloy is granulated, as usual, but not too fine, and then mixed with a little water and cream of tartar (as free from lime as possible) into a paste. To each two hundred parts of the granulated alloy is added one part of ignited oxide or nickel, and the articles are laid in it. After boiling a short time, they become beautifully plated. Some fresh oxide of nickel must, of course, be added from time to time. Brass and copper articles can easily be plated in this manner without previous preparation, those of iron must first be copper-plated. By adding some carbonate of nickel to the above bath, or to a common white bath, and boiling, a coating richer in nickel is obtained, and darker, varying in colour from that of platinum to a blue-black, according to the amount of nickel salt added.—*Man and Builder.*

To Correspondents.

H. W.—The Photographic Exhibition in London, to be opened in October, is held by the Photographic Society of Great Britain. Full particulars have not yet been issued, but will be published in our own pages and in the Journal of the Society. The Honorary Secretary, Mr. H. Baden Pritchard, may be addressed at the Chemical Department of the Royal Arsenal, Woolwich.

B. S.—There are many methods of treating glass so as to screen off direct sunshine, but none that we know of which will also effectually resist the damp of a leaky skylight. Perhaps the most likely to present a long resistance to moisture is varnish in which a little oxide of zinc is mixed up, which, if stippled on the glass with a stiff hog's hair tool, will produce a semi-opaque screen.

W. W.—The formula did not appear in our pages, but we remember to have seen it somewhere, but where we do not recall. So far as our memory serves us, its chief difference from the ordinary iron developer consisted in the addition of alum and camphor, for the purpose, as Mr. Wilkinson alleges, of securing in the developer a similar density to that of the nitrate bath. The necessity for this similarity has been frequently pointed out before as necessary to secure a perfectly even flowing of the iron solution over the plate covered with silver solution.

W. C. MURPHY—The address of Loebertier and Co. is 60, Regent Street.

G. H. P.—There is no work devoted solely to these subjects. For printing you will find "Hearn's Practical Printer" excellent. There is no work devoted solely to enlargement. You will find the best information on the subject in various articles in our columns and in our Year-Books.

LANDSCAPE AMATEUR, referring to Captain Turton's letter in our last, would be glad if we could devote space to the expression of opinion—either our own or that of correspondents—upon the qualities of materials sent out by different photographic houses, as it is very annoying, he thinks, to "buy various things which turn out quite differently to what buyers had been led to believe." He has, for instance, "bought many samples of dry plates, and never obtained a good negative from any of them; lenses which failed to cover sharp to the corners of the plates of the size for which they were sold; apparatus defective in many ways, and chemicals which worked badly." If he "or some one else more experienced were allowed candidly to state these facts, it would save others from being victimized." Our correspondent must see on a moment's reflection that such a course would be unreasonable in the last degree, and doing a serious injustice, to permit any tradesman to be injured on the opinion or experience of an individual. Just imagine such a course being adopted in ordinary journals in relation to the articles of general consumption. Why the law courts would be kept occupied with libel suits? Besides, the aims and duties of our journal are chiefly confined to the science and art of photography, and we avoid questions connected with its commercial aspects.

J. G. L.—The existing patent laws were passed in 1852. Previous to that date the law was much more defective than it is at present. A separate patent was required for each of the countries constituting the United Kingdom. That for England cost from £100 to £120, for Scotland £10, for Ireland £120, making a total of at least £320, all payable in advance. A patent for the United Kingdom can now be obtained on much easier terms. The provisional specification, which gives practically six months' protection, may be obtained for from six to eight guineas. On sealing the patent, and securing protection for three years, the cost is from five and twenty to thirty guineas. The three years may be extended to seven on payment of £50, and the seven years may be extended to fourteen on payment of £100 more. An amended law is now before Parliament, whether it will pass this season is quite uncertain, and if it pass it is very doubtful whether in ventors or the country will be any better off. At present the heavy fees paid for patents are the perquisites of law officers of the Crown, who appear to do little work in connection with patents.

F. L. J.—The red foggy deposit on the shadows of which you complain is aided by various causes. The best preventive we know consists in flowing the iron developed image as soon as developed with a solution of iodine made as follows:—Take two grains of iodide of potassium and one grain of iodine, and dissolve in an ounce of water. After flowing the plate with this, wash, and then proceed to intensify. The red deposit which appears during intensification in warm weather never visits the plate which has been so treated. The best mode of dealing with a negative which is spoiled by this red deposit in the shadows is to treat with a weak solution—say one grain to the ounce—of biiodide of mercury. This very slightly intensifies the image, but it converts the red deposit, which, being very non-actinic, prints white, into a thin white deposit, which does not in any appreciable degree obstruct the passage of light in printing.

R. F. L.—It is not at all improbable, as you suggest, that emulsions may eventually supersede plates prepared in a bath, but not yet. The first allusion to an emulsion was, so far as we remember, made in our pages in 1860, when Mr. Hellini made an oddly empiric mixture of various haloid salts and salts of silver in varnish. He showed us some imperfect positives alleged to have been produced by the aid of these mixtures. The next allusion was published in France, when M. Gaudin attempted to produce emulsions which he styles "Photogens." This, so far as we know, was not successful, and was not followed up. Captain Dixon subsequently patented a similar idea in this country; but nothing came of it. The first successful application of the idea of mixing the sensitive compounds in collodion, and forming an emulsion for producing negatives, was that of Messrs. Sayce and Bolton. About the same time we first made an emulsion with chloride of silver in collodion for printing purposes. We had frequently experimented years previously with emulsions of bromide and iodide of silver, and obtained pretty good negatives, but without sufficiently satisfactory results.

B. D.—It frequently happens that one thickness of flashed yellow glass is insufficient in the dark room window, owing to imperfections in the flashed surface. Try two thicknesses.

R. H. COURTENAY—Thanks. We will bear in mind your requirement.

Several Correspondents in our next.

The Photographic News, July 6, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

PHOTOGRAPHY IN MEASURING THE FORCE OF EXPLOSIVES—
THE ELECTRIC LIGHT FOR PRINTING.

Photography in Measuring the Force of Explosives.—The war on the Danube and in the Black Sea calls to mind once more the part which photography has taken in the elaboration of submarine warfare. Most of our readers are acquainted with the earliest use of the camera in connection with torpedo defences, when employed at Venice, where a *camera-nucula* was used to record the means taken to protect the harbour. Since then photography has been largely employed in this country for ascertaining the comparative explosive power of various compounds under water, and also in impartially recording the amount of damage done by different charges. It is well known that during the past few years gunpowder has been pushed into the second place, so far as military and naval mining is concerned, and even for industrial and blasting purposes gun-cotton, dynamite, and lithofracteur are now-a-days very frequently used, especially in the Colonies and America. All these substances are alike chemically, that is to say, that the nitro-glycerine which is the active principle of dynamite and lithofracteur is a nitro-compound, and may be considered very much as a liquid gun-cotton. This latter, as every photographer knows, is made by allowing strong acids to act upon cotton, and nitro-glycerine is prepared in the same simple manner, namely, by allowing glycerine to fall drop by drop into nitric acid. In this country we favour gun-cotton for mines and torpedoes, but abroad it is the nitro-glycerine compounds which are mostly used. To discover the explosive force of these and gunpowder, picric powder, and several other inventions, photography was employed. In submarine warfare two important points have to be considered, namely, how much water a charge can displace and how far a cushion of water of a certain thickness is capable of annulling the effects of a shot. It has been found, namely, that an ironclad is not safe from the explosion of a heavy torpedo unless a cushion of air of no less than forty feet intervenes between the floating hull and the source of destruction, while a Whitehead or fish torpedo is rendered harmless by a much less interval. The depth at which a charge is exploded has, of course, also considerable influence upon its effects, so far as shock or displacement of water is concerned, and by photography it has been possible to register the various influences exerted by depth in a very striking manner. Every time an explosion of this kind occurs, water is thrown up in the form of a cone, and this cone represents the amount of water displaced. If you know the measurement of its base, and are acquainted with the height to which the water has been thrown, it remains a comparatively easy matter to calculate the cubical contents of the bulk of water thrown into the air. To register this momentary eruption of water the camera is brought into play, and with exceedingly good effect, for it is in the main due to the photographic records of these eruptions that the comparative force of the various explosives has been arrived at. A five hundred pounds charge sunk to a depth of thirty feet, which throws into the air fifteen hundred cubic yards of water, must obviously have exerted far more energy upon explosion than another of the same height and at the same depth which only displaces a cone equal to one thousand cubic yards. In this way we have arrived at the conclusion that gun-cotton is equal, if not superior, to any other explosive, while its use for such purposes is particularly convenient. As we have said, the depth of water materially influences the displacement of water. Thus a photograph of the explosion of ten pounds of gun-cotton in ten feet of water shows as a graceful cone, or rather column, of water one hundred feet in height, but

then the base is a very narrow one; while four hundred pounds of gun-cotton exploded in twenty-seven feet of water is registered by a photograph representing a column only eighty feet in height, but in this case the base of the volume of water is upwards of one hundred and thirty feet. We shall not trouble our readers with any more technical details, and have, indeed, only referred to the above to prove the real importance of photography in connection with this modern branch of warfare, and to point once more to the wonderful applications that have been made of the process in the furtherance of war science. In a stereoscopic view of the *America* hulk, which we have before us, and which was one of the earliest of the torpedo explosions registered by photography, it is possible to see actually how the hull of the vessel is momentarily poised by the energetic action of the charge, and how the mass is lifted by the destructive agent. There is nothing very wonderful, perhaps, in the depiction of such an event, for photography has since then done wonders for science; but it is a matter, nevertheless, to which we are justified in again calling attention to show how valuable is the art-science in its proper application. Chevalier, the inventor of the photographic plane-table, had a scheme whereby he hoped to make use of photographic images to enable him to direct the firing of guns as well at night as by day, so that a bombardment might be continued after dark, and the enemy thus prevented from repairing his damages. Whether, had he lived, he would have been able to have brought his scheme to a successful issue now matters little, but we have instances enough before us to show that photography has already materially assisted in war science, and bids fair to render still greater services to the soldier and sailor.

The Electric Light for Printing.—According to Dr. Vogel, photographers are again making use of the electric light, a gentleman at Prague, Mr. Winter, having lately purchased a machine for his studio, the price of which, we are told, is £150. The electric light, which formerly used only to be produced by means of a powerful Grove battery, is now more conveniently generated from a magneto-electric machine, the construction of which has recently been much improved. Indeed, at the present day, to obtain a powerful light, it is only necessary to have a powerful steam-engine, for it is now a-days simply a question of grinding out electricity. When magnets were first made use of to generate electricity, the machines were very unwieldy affairs, for a very large magnet indeed is required to give a spark by merely disconnecting the rod, or armature as it is termed, from the poles. This was the first form of permanent magneto-electric machine, and then Wheatstone conceived the idea of revolving the armature very rapidly close to the magnet, or, in other words, in the field of the magnet. In this way a far stronger electric current was evolved from the machine, but still not strong enough to give a light. Round the iron armature was twisted copper wire, and this, again, was an improvement: but it was not until Wilde took the matter in hand that any great stride was made. He employs two magnets, and the electricity evolved by one is permitted to circumvent the other magnet, which is then capable of generating a very much more powerful stream of electricity. In Gramme's machine, which is greatly used in France, the armature has no iron, but consists simply of a skein of copper wire. The Gramme, the Wilde, and also the Siemens machine are all capable of giving electric lights. After the cost of the apparatus and the steam-engine, the expense of the light is represented by that necessary for keeping the engine going. Dr. Vogel tells us that he has tested the electric light photographically, and that at nine inches distance from the carbon points (rather near, by-the-way) it is capable of producing a carbon impression in seven minutes. One can hardly get at any data from this statement, but, according to our experience of the electric light, the latter, generated by a two-horse power engine,

is but one-twenty-fourth as strong as sunlight on a summer's day at eighteen inches from the source of light. In other words, a print which would be produced in five minutes in full sunlight would require as much as two hours' electric illumination if exposed at a foot and a half distance from the points. Other questions, such as that of decentralising the rays, would have to be gone into in case such means of printing were adopted by the photographer.

PHOTO-STEREOTYPING (PHOTO-ENGRAVING).

A SUBSTITUTE FOR WOOD ENGRAVING.

BY DR. ADOLPH OTT.*

WITH regard to the *modus operandi*, it is, of course, kept secret, but the history of a plate has been stated thus by one of the above-named companies:

"The subject—a properly prepared drawing or print—goes to the photograph gallery, where a negative is made in the usual way, except that it must be more perfect than any other known to the photographic art. The negative, having been duly examined, is forwarded to the secret department, whence issues a plaster of Paris mould, which is sent to the stereotype foundry. The substance in which it is cast is ordinary stereotype metal, with some modifications, the constituents being mixed in our own works. Coming out of the 'cast,' the rough plate is shaved to the proper thickness, and sent to the printer to be tested. When passed it is taken in hand by the finishers, who are for the most part regular wood engravers, who deepen the wider spaces, and touch up any portions which may not have come out sufficiently perfect. Then clean and file proofs are taken, the former to be sent to the customer, and the latter, properly numbered, to be pasted in a scrap-book for reference, and the plate is delivered to the blooker, to be mounted type-high, when, after a final examination, it is ready for use. It may be printed from direct, or, if desired, electrotypes or duplicate stereotypes may be made from it in the usual way."

From this it seems that a plaster of Paris mould is taken from the gelatine relief, and it is evident that from the first cast a second must be taken, which is stereotyped. We prefer, therefore, to call the process photo stereotyping, and not photo-engraving. Useful information on the preparation of gelatine plates may be found in the German work of A. Martin, *Handbuch der Email-Photographie und der Phototypie oder des Lichtdrucks* (Weimar, 1872, B. F. Voigt), and *Hints on Electrotyping and Stereotyping* have been published by the celebrated firm of R. Hoe and Co., New York, who also furnish the necessary apparatus for these processes, except, of course, for the purely photographic parts.

We will here remark that, according to our own observations, the gelatine relief is better brought out by using a very dilute solution of ammonia instead of pure water, and, in order to prevent the adhesion of the plaster of Paris, the relief plates should be soaked in a solution of protosulphate of iron (40 grains to one ounce of water) to which a little glycerine has been added.

We had lately the opportunity to visit one of the above-named establishments in this city, and were really surprised at the diversity of applications and the rapidity of execution which this new process allowed. The accuracy is absolute, and, of course, every picture can be reduced or enlarged at will. Various drawings may also be combined and transferred on a plate in relief, and, where an original illustration is to be made, the draughtsman also draws an advantage from the fact that the sketching on paper allows him a much greater freedom of execution than to the xylographer, who has to work on a most resistant material, box-wood.

With regard to the rapidity of the manipulation, it is well known that the chemical effects of the sun take place very quickly, and, although many operations have to be

executed which have nothing in common with the photographic art, it can safely be stated that the production of a relief from the most complicated drawing will only require as many hours, while the same work might occupy as many days or weeks of a skilful engraver's time.

The weekly pay-roll of the Photo-Engraving Company contains over sixty names, and it is estimated that, by the aid of their system and machinery, they can execute annually an amount of work which it would require the labour of one thousand wood engravers to accomplish by hand.

By the application of artificial light—oxycalcium, magnesium, or electric light—the operator is also independent of the sun.

Is it possible to obtain also gradations from light to shade (half tones) in the same manner as in photography? Most certainly; but, owing to the fact that the relief is not in one and the same plane in such a case, a cliché or stereotype plate of this kind could not be used in the steam printing press. In the new art these gradations must be produced in *lines*; however, it is already possible, by means of the formation of a grain, as in lithography, to print half-tones directly by the steam press. The grain lays here, as on the stone, on *one* plane. We shall, therefore, soon have illustrated journals wherein nature is reproduced without the least aid of the draughtsman. What an inestimable boon for literature and science! The most important illustrated journals of the metropolis make already an extended use of photo-stereotyping, at present yet in the manner of xylography, but the hearers present will, no doubt, have observed that the illustrations of European magazines, which arrive towards the end of the week, can be found at the close already in American journals. To the dissemination of art and the artistic culture of the masses photo-stereotyping will be of the greatest benefit, in so far as works of art, which only were accessible to a small circle of connoisseurs, can, ere long, be purchased by almost everybody. Thus one improvement is initiated by another in order to render photography what it should be, a universal reproducing art!

THE INTENSIFICATION OF CARBON PRINTS.*

OF the large series of silver compounds which it would be possible to use for intensifying the carbon image by reason of the beautiful and intense tone imparted, I have referred to a few only. Those I have mentioned will, nevertheless, I have no doubt, suffice for the purposes of the carbon printer. Daylight has no influence upon the silver intensifier in this connection, and the manipulations may, therefore, be conducted at any time without fear of consequences.

The great advantage of silver solutions is, that they never fog the image, and even free defective pictures from their faults in this particular. This property of silver is easily accounted for, for the image soaks up the solution, according to its thickness; in washing, it is taken out of the lighter parts to which the fogged portions belong, so that the nitrate of silver only works thoroughly in the highest reliefs, and only deposits its colour in those places. This is a general rule in intensifying, which, however, is here peculiarly apparent. The best results will be found to be afforded by pyrogallio acid and nitrate of silver, which bring about warm purple-black pictures. To lighten up carbon pictures, after such treatment, when this is necessary, a solution of hyposulphite of soda will be found useful. Cyanide of potassium in strong solutions sometimes injures the pigment film, and, for this reason, is not to be recommended.

Intensifying with Cobalt, Uranium, and Nickel.

Chloride of cobalt and sulphide of potassium or sulphide of ammonium give an intense black with brownish tone.

* Continued from page 303.

* Concluded from page 307.

Chloride of cobalt and bichromate of potash or ammonia give a yellowish-brown film.

Yellow prussiate of potash and nitrate of uranium yield a warm sepia-brown.

Chloride of nickel and sulphide of potassium or sulphide of ammonium impart a warm black.

Chloride of nickel and red prussiate of potash colour the pigment image brown.

Divers Colouring Matters for Pigment Pictures.

Baryta water, or lime-water and alizarine, dissolved in alcohol, colour carbon prints violet.

Acetate of lead and alizarine in ammonia colour prints purple-red.

A solution of alizarine in caustic alkalies give in proportion to the amount of water that they contain a series of violet and purple tones.

Aniline red in alcohol is not suited for colouring, especially when in the enlargement process.

Sulphate of zinc and alcoholic solution of coralline, with an addition of ammonia, yield a rosy-red.

Solution of coralline diluted with water, and treated with ammonia, colours pigment prints of a carmine red.

Ordinary solution of coralline dissolved in alcohol gives red pictures.

Logwood solution colours blue.

Logwood solution and bichromate salts give a very agreeable greenish tint, which is very suitable for colouring landscape pictures.

Acetate of lead and purpurine in ammonia colour purple-red.

Purpurine dissolved in a hot solution of alum renders the prints cherry red.

Purpurine dissolved in caustic alkali imparts a carmine red to carbon images.

All the above alkaline solutions should only be employed greatly diluted with water. Clearing up liquids are not necessary, as any tint may be secured by watching the action of the re-agents, and washing off as soon as the proper tint is secured, continued rinsing having the effect of lightening the colour.

To demonstrate more clearly the different tones secured by the various re-agents I have described, a series of carbon prints showing all the various tones that are obtainable has been forwarded by me to the Photographic Society of Vienna.

To secure an even tinting throughout the image, it is necessary, before treatment, to ascertain that the degree of dryness is the same throughout the picture. To ensure this, the carbon print should either be treated with the intensifying fluids immediately after development, or the operation should be postponed until the image has become thoroughly dry. An image which is only partially dry when submitted to the action of the intensifier frequently becomes patchy by the unequal soaking-in of the re-agent that is applied.

The intensifying of the print is brought about either by one treatment, or by successive applications of the liquid to the film. The intensifying liquid is poured over in the ordinary way, and in the case of a dry image this is first moistened in water, so that the action of the liquid may be exerted all over the surface at the same instant. If several solutions are employed in the operation of intensifying, then the surface of the image should be washed with water between every application, otherwise there will be formed over the surface a fine precipitate resulting from the action of the liquids one upon the other. In this case the liquids cannot penetrate well into the film, and the result is an uneven or imperfect result.

Large pictures, or those which it is desired to handle with particular care, are best treated by being placed in a dish containing the intensifying bath. The image is put into the liquid face uppermost, so that the action of the reagents may be strictly watched. Too lengthy a treatment hardens the image too much, and if permanganate of

potash is employed, then the details of the picture suffer in course of time. As a rule, the intensifying process should last from five to ten minutes. In the event of the pigment picture not becoming dark enough, it behoves the operator simply to repeat the process until the desirable result is obtained.

The intensified pictures do not, as a rule, require treatment in the alum bath, nor is it advisable that the latter should be applied, as its action is sometimes injurious to the colour. After proper intensifying the picture is washed carefully in clean water in order to remove any superfluous liquid from the film, as also to free the latter from precipitates which may have been formed upon it.

Carbon prints which are to serve as negatives in the enlarging process should neither be waxed nor have collodion or gelatine applied to them, as every irregularity in the waxing or any imperfection in the collodion or gelatine is reproduced and rendered more prominent in the enlargement. In intensifying, with few exceptions, which I have already alluded to, the collodion and gelatine, when touched by the intensifier, not unfrequently give rise to fogging. With a good tissue neither collodion or gelatine are necessary to produce adhesion upon the glass, for when developed the image sticks very firmly indeed. In his work on carbon printing, however, Liesegang suggests the coating of glass plates previously with dilute gelatine solution dipped in alum, as a means of preventing the reticulation of the tissue, a defect with which the carbon printer is at times troubled. I am not altogether of the same mind, for a good pigmented tissue should not, and does not, yield reticulated impressions, when even the glass is perfectly free from all sorts of preparations. Reticulation has never been observed by me upon collodionized or unprepared plates, unless the tissue has been acted upon by very alkaline or acid solutions; it is well known to me, however, that such pictures as are developed upon gelatine become reticulated by reason of a number of soluble gelatine molecules being washed away during transfer, and thus impart a net-like aspect to the image. The same defect may result from air-bubbles between the tissue and the transfer basis. In this case the cause of defect must be looked for in those bodies which prevent the immediate contact of the two surfaces.

COLLECTION AND RECOVERY OF WASTES.*

In the various processes of photography in which nitrate of silver is used, the per centage of what is called waste is very large, but with proper care and management this may nearly all be recovered, and thus keep the actual consumption of silver down to a very small figure. We are convinced from the appearance of many operating-rooms that sufficient care is not exercised in saving the dripping from plates in the negative department.

In the dark-room the careful operator has in mind the saving of silver in every movement he makes. In making up and filtering his bath, he takes the precaution to spread some old newspapers on the floor to catch any drops of silver that may fall. These papers he keeps for that purpose.

With waste blotting-paper he wipes any drippings from the bottles, the bath, or the plate-holder. He drains his plates well when they come from the bath, and then uses plenty of blotting-paper to catch any further drippings in the holder. He has a box padded in the bottom with blotting-paper, in which he carries the holder from the dark-room to the camera. He saves his first washings, after developing, in a tank prepared for the purpose, and scrapes the films from all plates that are failures. This last is best done by placing the plates in a dish or tub of water till the day's work is over.

In the printing department the same precautions are observed in the use of the silver bath, as in the dark-room.

* *Philadelphia Photographer.*

Where the paper is hung to dry, waste paper of any kind is placed on the floor to receive the drippings. All cuttings from the sheets or prints are carefully preserved, together with blotters, filters, and scraps of every kind that have been stained with silver. The first washings of the prints which show a milky appearance are carefully saved in a large tank or barrel; old toning baths are also saved for the gold; and finally the fixing bath, which performs the last chemical operation for the prints, is deposited in a barrel, tub, or bottle, together with the negative hypo bath from the dark-room.

To the developer washings a small quantity of a saturated solution of salt may be added every night, and the clear water drawn off every morning from a faucet placed at a proper distance from the bottom of the tank, according to its size. The print washings are treated similarly by adding every night one pint of a saturated solution of salt to every ten or twelve gallons of water used, stir well, and draw off in the morning or when full. To the old hyposulphite baths may be added from time to time a few lumps of sulphuret of potash, or the same in solution. A black precipitate of sulphide of silver will be formed, which will settle and leave the clear water to be drawn off. An excess of sulphuret will do no harm.

When a sufficient quantity of waste has collected according to the foregoing treatment, the various kinds are then to be prepared for reduction. This may be done by freeing the residues from the surplus water as much as possible, and putting them in wide-mouth bottles, each kind distinctly labelled, preparatory to sending them, together with the waste paper, to a refiner, provided the photographer does not care to undertake the work of reducing it himself. But we would caution any photographer who sends his waste out to be careful that it goes into the hands of reliable parties. On no account deliver it to an agent of some so-called refining company who may come along and offer to do it for eight or ten per cent, for in most cases they are frauds, and if ever you receive anything, the amount will be so small that you will not feel repaid for the trouble you have been to in saving your waste. Either send it to somebody you know that will not do it for less than from fifteen to twenty per cent, according to the quantity, or else do it yourself by the processes which we propose to give you here.

The black mudlike mass which will be found in the bottom of the developing tank, after the water has been drawn off as closely as possible, should be spread upon a filter and allowed to dry. A filter for this purpose is made by stretching stout muslin over a frame or hoop of any size sufficient for the purpose. The drying is facilitated by placing it out in the sun, and occasionally turning the mass over and pulverizing it as it dries. If there be much water in this residue, it may be better to spread sheets of filtering paper over the cloth before placing the mass upon it. When it is thoroughly dry it is ready for the crucible. Collodion films are to be spread out and thoroughly dried, when they may be placed in an iron pan and burned. The remaining ashes are then ready to be prepared for the crucible.

The print washings are collected and dried in the same manner as the developer residues. Should the chloride of silver fail to settle after the salt is added and being well stirred, it may be precipitated by the addition of a mixture of slacked lime and water of about the consistency of thick whitewash; this is also assisted by the addition of a small quantity of a strong solution of sulphuret of potash.

Residues from hyposulphite fixing baths are freed from the supernatant liquid by decanting the latter; the precipitate is then washed well with warm water, and permitted to dry. This is sulphide of silver, and to prepare it for reduction it must be roasted. This is done by placing it in an iron pan or shovel, and submitting it to the heat of a brisk coal fire. This should be done in the open air, or in the draft of a large chimney. When the mass assumes a red heat and the vapor ceases, it may be removed from the fire and allowed to cool.

Print clippings, filters, and all waste paper which has absorbed silver, are to be burned. This is facilitated by sprinkling the paper, especially that which is poor in silver, with a solution of nitrate of potash (saltpetre) three ounces, water eight ounces. When dry, they are burned in an open grate or stove. Care must be taken that the draft is not too strong, or too much paper put on at once, to cause the ashes to be carried off with the flame and smoke. Do not try to hurry it, and you will be repaid for your patience. If there be a large quantity of paper an occasional raking out of the ashes from the grate will admit the air and assist combustion.

Having prepared the several residues, the next in order is to reduce them to metallic silver. This is done by fusion, assisted by various saline mixtures which are called fluxes. A different flux or different proportions are used for each of the different kinds of waste. In each case it is important that the residue and flux be ground together in an iron mortar as fine as possible, after being mixed in the following proportions:

For Chloride of Silver.—This may be precipitated from old baths or print washings.

Carbonate of potash	16 ounces
Powdered resin	2 "

Take of this flux half the weight of the chloride. Thoroughly mix and grind them together as before directed; then fill a Hessian crucible* about three-quarters full, packing it in closely. A layer of common salt sprinkled over the top tends to prevent boiling over during the fusing process. The carbonate of potash may be used alone in this case, but chloride of silver volatilizes, and portions of it escape before the reduction has commenced; the resin combining with it prevents this.

Ashes from Collodion Films.—These consist mostly of iodide and bromide of silver, and may be mixed in the proportion of five ounces of ashes to four ounces of the following flux:

Carbonate of potash	8 ounces
Bicarbonate of soda	1 ounce

Prepare the crucible the same as before.

Developer Precipitate.—This having been prepared as previously directed, mix with equal parts of the following:

Carbonate of potash	5 ounces
Nitrate of potash	1 ounce

Place in the crucible the same as before.

Paper Ashes.—These are to be sifted through a fine sieve to free them from bits of glass, nails, &c. Any beads of metallic silver remaining on the sieve should be returned to the ashes. Mix these with equal weight of

Carbonate of potash	4 ounces
Bicarbonate of soda	1 ounce

Prepare the crucible as before directed.

Roasted Sulphide of Silver.—This compound is the most difficult of all to reduce. The following flux has been proved to be excellent:

Carbonate of potash	15 ounces
Bicarbonate of soda	10 "
Nitrate of potash	6 "

Mix eight ounces of sulphide to seven ounces of flux, and only half fill the crucible, as the mixture seethes violently during reduction.

Reduction.—For this purpose a small furnace, or a stove with a good draft, should be used. An ordinary coal fire answers well, though some prefer coke or charcoal, as they produce a quick heat, and make less ashes to clog the fire. The crucible should have a cover, and be buried in the coals. As the contents of the crucible fuses and settles, more of the mixture may be added with an iron spoon, a small quantity at a time, till the crucible is filled with the molten mass. Then cover it and subject it to a white heat for about half an hour. To ascertain if the reduction be complete, take a stout iron wire and stir the mass. If reduced, it will seem

* These come in nests, and may be had of any druggist.

perfectly liquid without any feeling of sand or grittiness. The fused silver may also be felt at the bottom by its greater density and resistance, and when the wire is with drawn a smooth black glass will be found upon it, free from sand or roughness. If an examination answers these conditions the crucible may be removed and allowed to cool, and is then broken with a hammer, when a button of pure metallic silver will be found in the bottom.

These processes may seem tedious and troublesome to those not familiar with them, but they are not really so. All of the work can be done at odd times and during stormy weather, and the extra cost for materials, beyond what may be found in every gallery, is trifling.

Any photographer who will practice economy in collecting his waste, and then reduce it himself according to the methods we have described, will find a handsome balance to his credit in the waste account at the end of the year.

A USEFUL DEVELOPER.

MR. D. E. SMITH gives the following in the *St. Louis Practical Photographer* :—

"Throw equal quantities of protosulphate of iron and the double salt of iron and ammonia into a jar, and fill up with water. Shake from time to time, so that the water may be kept filled with the salt. Let this be a stock solution, easily replenished with water or salt, as occasion requires. In another jar keep a saturated solution of sulphate of magnesia (epsom salt). To make your developer measure out of the

Iron solution	2 ounces
Sulphate magnesia	2 "
Acetic acid	3 "
Water	16 "

Vary in same proportion for larger or smaller quantities. A slight modification of the acid and water may be needed to harmonize with the temperature and length of exposure. I have used no alcohol whatever in my developer for the past year, and have experienced no difficulty in flowing my plates."

COLOURING PHOTOGRAPHS.

THE process of colouring photographs is by no means so difficult a matter as you might at first have supposed. There are certainly some obstacles to be encountered, but you will soon overcome them, provided you will sit down with a determination to overcome them. You must be patient and persevering, go gradually on, endeavouring to improve with every stroke you take, keeping the tints of the face and background light, gaining colour and depth by repeatedly working over them; the effect thereby produced will be infinitely superior, and far more artistical, than if you had at once laid on the colour as strong as required. Avoid, as much as you possibly can, all washing out of tints after they have once been put on, for the surface of the photographic paper is of a delicate nature, and will not bear much rubbing. Again, you must not feel disappointed if your first efforts do not turn out altogether as satisfactory and pleasing to you as you had hoped for. Do not give up in despair, but go on, persevere, and good coloured pictures will be your reward in time. Be particular in procuring good photographs to work upon and experiment with; also, good colours and pencils to work with, for your success will in a great measure depend upon these. Do not be over anxious to get a very high finish to your work at first, which, after all, does not constitute excellence or perfection, for a good picture may be satisfactory without it, while a very bad one may have it in excess. The highest finish is labour in vain, unless at the same time there be preserved good lights and shadows, which actually make up a good, finished picture.—*Practical Photographer*.

HOW TO SIT FOR A PHOTOGRAPH.

AFTER having arranged the preliminaries as to style, price, &c., enter the operating room and inform the operator that you have but three minutes to catch the train—persuade him, if possible, to sit you in advance of two or three others who have been patiently waiting; get vexed and pout if he declines to do so without their consent. Then retire to a seat in the reception room and cultivate a view of thought best adapted to make you miserable.

When your turn comes, suddenly recollect that your hat, cloak, &c., must be removed, and that your hair needs crimping or re-arranging; wonder why you had not so employed yourself while waiting; but, no matter, console yourself with the idea that you are paying Mr. Skylight back in his own coin by making him wait.

If your face is long and slim, be sure to do your hair up high "à la pompadour;" this may make the face look a little longer and slimmer—but, no matter, follow the prevailing style, and blame the operator for all that is not as your fancy pictured it.

Should your neck be a trifle long, wear a dress cut low, or a turn-down collar. If it is the reverse, wear a high ruffle "à la Queen Elizabeth." Should "Old Glasseye" suggest a ruffle for No. 1 and collar for No. 2, think how stupid he must be not to know what folks are wearing this fall.

If the figure is tall and slim, wear a long-waisted dress with a skirt as scant as you can, but possessing a long trail; this will make you rail in appearance and rail at the artist too.

If the extremities of your mouth should be unfortunately near your ears, don't allow the artist to make a profile, because such a view would only show half of its actual capacity for buckwheat cakes, &c.

If the case is otherwise, insist on a profile, because a lady friend of yours had a side view taken which every one admires. Should there be a liberal supply of humanity in the make-up of your nasal organ, object all the more to a full view of the face.

When you are about to be sacrificed, surprise your tormentor with some new and original phrase, such as, "I would rather have a tooth extracted." When he attempts to pose you, object to the position, or, better still, bring in three or four lady friends and induce them to sustain you in your objections, get them to fuss around you as possible, and don't for a moment forget you are seated in a dentist's chair. Totally ignore the artist, so he will be responsible only in the case the picture is a failure.

If a child is to be photographed, wait till about sundown, or rise unusually early, and come before breakfast—you are aware that the best light for "the little ones" is between 10 a.m. and 2 p.m., but no matter about the light—suit your own convenience. If the child is less than two years old, insist on having it taken standing, and, to make matters still more difficult of accomplishment, put on a dark dress. If the child is older, commence a week or two before the picture is to be made to drill it in positions; teach it how to hold its mouth, and don't forget to tell it repeatedly not to be afraid of the artist, thus conveying to the child's mind the idea that something terrible will happen, and that a monster will have charge of the ceremonies.

The above is not a rare experience in the profession, but quite a common one, and the moral is obvious. If you expect a natural picture, do not get yourself up in a style entirely foreign to your everyday appearance. Discard gew-gaws and so on; dress the hair and person becomingly; and, finally, assist the artist in his by no means easy task. He must have your entire support and confidence, and the utmost good feeling must prevail throughout the operation, or the inevitable result is a failure.—*New Britain Record*.

PHOTOGRAPHY IN THE FRENCH MUSEUMS AND GALLERIES.

ACTING upon the recommendation of a Commission, the Minister of Public Instruction and of Fine Arts in France has determined to permit the indiscriminate employment of the camera throughout the whole of his domain. Every museum and gallery under his sway may now be invaded by the photographer, provided the latter obeys the rules and regulations drawn up for his guidance and for the proper protection of the property of the public. In no other country has such open access been permitted, and there can be little doubt that the dissemination of knowledge in this way, by permitting works of art and antiquity to be reproduced, and thus brought within the province of those resident at some distance from the collections, will not fail to bring forth fruit. France leads the way fearlessly, and without hesitation; we can only hope that so good an example will be speedily followed by other European nations.

The regulations drawn up for the guidance of those desirous of using the camera in public galleries and museums will be of interest to our readers, and therefore we make no apology for translating them and reproducing them here. They are as follows:—

1. The employment of photography is authorized in the scientific and literary establishments under our control.

2. Any one desirous of obtaining permission to reproduce, or cause to be reproduced, by photography the objects preserved in any of the establishments must make a request in writing to that effect, to the head of the department. In this letter must be specified:

a. The objects of which negatives are desired to be taken.

b. The nature of the work for which the clichés are required, and its destination.

c. The name and address of the operators.

d. The contemplated duration of the operations.

e. An engagement to conform to the regulations of the department.

f. A declaration that the petitioner assumes absolutely all responsibilities which may be entailed by the reproduction.

3. Permission may be given by the head of department, or, in case of refusal, by the Ministry; the authority does not in any case create a monopoly.

4. The head of department will refuse authority in any case where the reproduction might jeopardize the preservation of the objects under his care, or in any way affect public morals.

5. The head of department will not take notice of requests for the reproduction of objects to be obtained in commerce.

6. The operators admitted into the galleries of the State must not bring with them either fire or inflammable or explosive substances. They may only make use of films prepared beforehand by a dry process. They will only be permitted to expose in the galleries; all other operations must be conducted outside.

7. The heads of departments will determine the days and hours for opening the establishments. They will also determine the order and time in which operators armed with authority are to be admitted.

8. All the operations will be conducted in the presence of an officer of the department, who will see that the objects reproduced suffer no deterioration.

9. The head of department will impose any measures which he may deem necessary for the proper preservation of the objects; he may especially prevent the same from being handled by the operators, and stipulate that the objects should be protected by a glass during the operation.

10. The Administration and the heads of departments will prescribe measures to ensure that the proofs obtained are only the reproduction of objects belonging to the State collections.

11. Any operator infringing the regulations will be excluded from the building, as well as those who compromise the safety of anything in the collections.

12. Persons permitted to reproduce by photography any objects in the State galleries or museums must comply as follows:

a. They must deposit at the Ministry of Public Instruction a good cliché of every one of the objects reproduced, the cliché in question bearing the producer's name.

b. They must forward to the department to which the object belonged two prints of every cliché.

13. The clichés deposited at the Ministry will become the property of the State, which may make use of them in any way that should appear desirable.

14. A central laboratory will be formed with the assistance of the Director of Public Works in one of the rooms appertaining to the Ministry of Public Instruction. This laboratory will serve the following purposes:

a. For the preservation of clichés deposited in accordance with law 12.

b. For the execution of photographic work, such as may be ordered to be performed by Government.

c. For the training of operators who may be deputed to act upon the public service.

d. For examining and inspecting stores of a photographic nature prior to their shipment abroad to the Colonies.

The above regulations are in the main very excellent. It will be noted that only dry processes are to be permitted, and these, we fear, will give some trouble where the museums are not well lighted. Wherever it is practicable, however, a studio will be attached to the gallery or museum, where proper exposure can be given. Although it is absolutely necessary that the objects should be jealously protected in every way, we fear that few satisfactory reproductions will be the result if the object photographed is covered with glass, as laid down in regulation No. 9.

PHOTOGRAPHING THE HUMAN VOICE.

DR. STEIN, of Frankfort, is already known to our readers as one who has done much in the application of photography to physical and physiological research. Our readers may remember the accounts previously published in these columns of Dr. Stein's successful method of securing photographic records of the pulse-beatings, and also of reproducing by photography tones such as are produced by tuning-forks and musical instruments.

Dr. Stein has now gone a step further. Our readers

have heard of the telephone, by the aid of which the voice of a speaker may be transmitted twenty miles by telegraph. With the assistance of Dr. Stein's apparatus his speech may be photographed or written down upon a sensitive plate in the shape of curves, or, rather, in the form of a serpent-like line. As the tones vary, so the waves of the line occupy more or less space, or are taller or shorter. Shrill notes or tones, where the vibrations are rapid, are represented by many steep waves; low, or bass tones, where the vibrations do not follow each other so rapidly, produce few waves in a line.

We think we can explain to our readers how Dr. Stein converts a speech into a wavy line. A membrane, very much like the head of a drum, is stretched before the mouth of the speaker so as to vibrate quickly or slowly, according as his tones are shrill, or bass. A metal band is at the back of the drum, and vibrates also; this band is in connection with an electric battery, and as it vibrates it makes and breaks contact with another metal band, to which it communicates a series of electric currents. These electric currents are communicated rapidly or slowly, according as the vibrations are rapid or slow, or, in other words, as the tones uttered are high or low. These electric currents pass to an electro-magnet, which sets in motion a little metal bar, attracting and repelling the same as rapidly as the vibrations pass. The reader must now imagine, perched upon this bar, a little screen, or diaphragm, having a little hole in its centre. Through this hole shines a light, the light making a tiny image upon a sensitive plate in a camera opposite. If the metal bar and the screen move up and down, as they will do when the vibrations commence, then the light-point makes an up and down image or stroke upon the sensitive plate. The sensitive plate is not at a standstill, however, but keeps gradually moving in a horizontal direction, and the consequence is, that the up and down stroke made by the light point partakes of the form of a curved line. This, in a few words, is the principle of Dr. Stein's mode of proceeding.

THE VISUAL PURPLE OF THE EYE.

WE have several times alluded in these columns to the so-called visual purple, or *seh-purpur*, as the German physiologist, Boll, terms it. This visual-purple is a coloured sheet at the back of the retina of the eye, and becomes impressed by light in the same way as a photographic film. The light must, however, be very intense to make an impression, and it was only by exposing a rabbit's eye in a dark room to the action of a ray of light coming through a shutter for three minutes that any image could be produced.

It has been a question how long the visual-purple remains after death. Boll found that a rabbit's eye immediately after death was in a position to receive an image quite as readily as when alive, and he asserted that he believed the visual purple to remain unbleached and photographic many hours after death. The German physiologist has been lately able to prove that in the human being such is the case for two hours and three-quarters after death, at any rate. The subject in this case was a criminal who was executed in Vienna on the 5th of March last, at a quarter past seven in the morning. The execution occurred in a badly-lighted yard, surrounded by high walls, and immediately after death the executioner, as is customary, closed the eyes of the body. Other means were then taken to keep light from the retina, and after an interval of a couple of hours an examination was made by Boll of the eye. A microscopic inspection at once showed the existence of the visual purple, so that the eye still possessed photographic properties, but no trace of an image was to be observed on the retina of the dead man. But even had a slight impression been bleached upon the purple film, say that of the prison wall, this would, nevertheless, have

disappeared again, since the membrane behind the retina possesses all the properties of a re-sensitizer, and would have restored the purple colour again in a very short time. That the visual purple does not lose its properties till some time after death may now be taken for granted.

So far as regards the possibility of an image existing on the retina after death, so as to be discoverable some hours subsequently, we may safely decide in the negative, judging from what we know of the *seh-purpur*. It is only, as we have seen in the case of the rabbit, where the object is very bright, or it is steadily reflected upon the eye for some time, that an image appears; and then the latter must be immediately fixed in alum, as otherwise the mucous sensitizer does its work, and the purple colour is restored. No doubt when the eye looks upon a very light object—the sun, for instance—and the vision remains persistent for some minutes, or seconds, afterwards, our eye has received photographic impression, but this is not likely to occur just before death. Only under such circumstances would it appear possible to secure a photograph upon the *seh-purpur*, or visual purple of the eye.

LANDSCAPE PHOTOGRAPHERS' BELT.

A CORRESPONDENT, Mr. H. Somerset Ware, sends us details of an ingenious contrivance which he has found convenient, and will, doubtless, be useful to others. It consists in a belt, with cells for holding bottles, so that each chemical is at hand for use, and in no danger of being broken, upset, or lost when out of use. The length of the belt will, of course, vary as the photographer is stout or thin. Mr. Ward's is two feet nine inches long, and five inches wide. We subjoin a diagram, with the bottles in place:—

No. 1 is collodion; 2, intensifying solution; 3, ten-grain silver solution; 4, strong iron developing solution; 5, weak iron developing solution; 6, fixing solution. The stoppers and corks must always be carefully replaced, or stopping might produce awkward consequences.

We append Mr. Ware's letter:—

"I intend the enclosed sketch to describe a plan upon which I have fitted up a belt to carry bottles, and it is an idea which may be of use to some of your readers who are fond of landscape photography, as owing to the bottles being suspended round the waist, they are more easily carried than in a box, the weight of which in itself is very considerable. It also enables you to lighten the dark tent by dispensing with some of the shelves; and it will be found a convenience to have the bottles near at hand.

"I bring this idea before you as I consider it to be a novelty, and knowing, also, that you are anxious to lay before your readers anything which may assist them to pursue photography more pleasantly.—I remain, dear sir, your obedient servant,
H. SOMERSET WARE."

FRENCH CORRESPONDENCE.

DESPAQUIS' PHOTO-ENGRAVING PROCESS—METHOD FOR OBTAINING GRAIN IN PHOTO-ENGRAVED PLATES—M. CHARDON'S WORK ON PURE BROMIDE OF SILVER EMULSIONS—THE COLLODION HE EMPLOYS—HOW HE MANUFACTURES THE PYROXILINE EMPLOYED IN HIS EMULSION.

M. DESPAQUIS is at present publishing a series of instructions connected with greasy ink printing, the details of which are not the less interesting because they have hitherto constituted a patented process, which has before been closed to the public. One portion of M. Despaquis' communication bears reference to photo-engraving, and your

readers will, I feel sure, be glad to learn something about it. M. Despaquis has observed, like all who have occupied themselves with this branch of study, that in an engraving it is necessary to have a grain inside the cavities, while the surface should be of a polished character in those portions destined to reproduce the whites of the image. He therefore set about to discover how such a result could be brought about. He applied to the metallic plate two films of gelatine, the first a thick one containing the grain, and the second thinner and absolutely free from grain. It is due to this second film that M. Despaquis is enabled to produce all the delicacy of half tone. His method of operating is as follows:—In one thousand cubic centimetres of water are dissolved two hundred grammes of gelatine; to this are added twenty grammes of liquid Indian ink and four grammes of powdered pumice, the latter being very finely ground and sifted through fine linen. Next, upon a plate of glass which has been waxed, he spreads a sheet of moistened paper, taking care to prevent the formation of air-bubbles. The solution of gelatine, previously filtered and maintained at a slightly warmed temperature sufficient to keep it liquid is then poured upon this sheet of paper. In this way a sheet is secured, covered with a thick film of gelatine having a very fine grain, uniformly spread throughout its body. When it is desired to make use of this prepared paper the second film is applied, and the sheet sensitized at the same time; to do this, it is immersed (prepared side uppermost) in a solution composed of:—

Water	500 cub. cent.
Gelatine	1 to 15 grammes
Bichromate of ammonia	15 "

After remaining in this liquid for some seconds the sheet is taken out, and by two of its corners (still prepared side uppermost) it is drawn over a gelatinized plate, previously prepared with ox-gall, so that later the paper may be easily detached. The sheet, dried in a locality where it is screened from daylight, is cut a little larger than the cliché, and placed underneath the latter. The exposure of the prepared sheet to the light should be about a third that necessary to give a carbon print. As in this latter process, as soon as the printing is finished, the impression is plunged into cold water, so as to transport the print, not to albumenized paper, but to a plate of polished steel or copper; it is afterwards put under pressure, and allowed to dry, and finally the image developed, as in the carbon process, with warm water. It is, indeed, treated as if it were a carbon print, rather more care being taken, however, because there is less adhesion between the gelatine and the polished steel. When the matrix-plate has been secured in this way, a mould is made, either in the hydraulic press, as in the Woodburytype process, or in a rolling mill, covering the plate with a double sheet of very stout lead. The mill must be worked two or three times, so that every detail of the image is reproduced in the lead. Finally, you produce by the aid of the electrotype process a counter-mould, which is the plate from which the printed copies are produced.

M. Willème, the inventor of photo-sculpture, who quitted Paris some years ago to establish himself at Sedan, has found out, it would seem, a very simple means of transforming the latent image which is formed in the camera into a visible picture. Thanks to the preparation of the sensitive film, which does not involve any variation of the ordinary manipulations, he renders the action of light apparent at once, so that it is possible to watch the progress of the operations until it is found convenient to arrest them. It is especially in the production of enlargements that this faculty will become useful. Some experiments are to be conducted in the studio of M. Carotte, and of these I hope to give your readers some account, together with further details of this interesting process.

Under the title of *Photography by means of pure bromide of silver emulsion*, M. Chardon has just published all the details of his process. In this work the author enters

into all the various matters, and gives the most minute instructions concerning the operations involved, and informs the reader, moreover, of the methods for producing the different products necessary in the process. Especially does he tell about the pyroxyline and bromides, and clears up much about them which before was exceedingly obscure. With M. Chardon, collodion—or, in other words, the mixture of pyroxyline, alcohol, and ether—is simply a vehicle destined to contain the various active salts, which remain so far without any reaction upon one another. In the preparation of the emulsion, if the proportion of emulsion be insufficient, then the bromide of silver formed by the addition of nitrate of silver is precipitated in part, and the result is a granular film which has no strength of cohesion. If, on the contrary, the proportion of pyroxyline in the collodion be too great, the film which is formed will be too transparent, and display a lack of sensitiveness. In this case the result will be clichés without vigour, which are incapable of being intensified. After numerous experiments M. Chardon has recognised the advantages possessed by a mixture of pyroxylines prepared one by immersion of the cotton in sulphuric acid and nitrate of potash (porous collodion), and the other by immersion in sulphuric and nitric acid with water added (resistant collodion). What distinguishes M. Chardon's work most of all is, however, the theoretical explanations, clearly and logically expressed, which he appends to the various practical results that are given.

ERNEST LACAN.

A FEW REMARKS ON PHOTO-ZINCOGRAPHY.

BY K. ELIE.*

REPRODUCTIONS of engravings and woodcuts by the aid of the camera are no longer attended with difficulty. But this is not the case when photo-zincographs are required from negatives taken direct from nature. M. Jaffé (of Vienna) and a photographer of Stockholm have both come forward at the same time with a similar method, the principle of which has, however, many drawbacks. By taking a picture through a net you obtain, it is true, large or small grain, which forms half-tone and shadows, but the direction of the points is never after the form of the pictures, and for this reason the images always appear flat; while further, the pronounced streaks and inequalities to be seen in the photograph of the net are not to be overcome. The main defect of the method consists in the circumstance that a point when etched and printed gives rise to more difficulties than a line. In etching, while a point is attacked from all sides, a line is only acted upon by acid from two sides. In printing, again, a point is not so deeply printed upon paper as a line, even when considerable care is used in the process. For this reason the softening of a sketch appears smeared, and the highest lights are abruptly isolated or cut off. In the so called English wood-cutting, in which points are allowed to stand, the printing is better, because the softening-off marks are deeper, such as are not to be obtained in etching.

For some years past half-tones have been secured in Paris in the following manner. Pigmented tissue is dusted over with asphalt so long as it remained moist, and was then printed through this dust under a negative. In this way clichés in half-tones are secured. These must, however, be printed with very little ink, should possess no open high lights, and for this reason, therefore, the pictures which resulted were never black enough in the shadows, nor pure enough in the lights. I would recommend to those who occupy themselves with similar processes to work in the manner following.

The negative, whether varnished or not, is covered with a solution of gelatine or glue; when this thin film of gelatine has dried, then a solution of asphalt is applied, to which a few drops of petroleum have been added, so

* *Photographische Correspondenz*

that in the end the asphalt coating may not be too hard. The asphalt film must not be too thick, but must still permit the whole of the details of the negative to be seen. A scraper is then taken in hand, consisting of fine sewing-needles, which on touching the negative film produces upon the asphalt parallel lines. With this scraper, or graver, the asphalt film is cut through, the lines being made to follow the principal contours of the negative. The lines thus scratched upon the negative are all over of the same strength; but when prints are taken from it, it is absolutely necessary that the lines which pass over the transparent portions of the negative should be broader than those which are drawn over the more opaque portions. I attribute this to the circumstance that by powerful illumination the open lines appear broader than when less light is used. Upon the perfectly opaque portions of the negative cross-markings may be scratched. In the sky or background of the negative the lines may be drawn by a linear-instrument.

THE PROPERTIES OF LIGHT AND COLOUR.

[THE "blue glass" subject has been pretty nearly exhausted, we think, but the following admirable summary of the properties of light and colour, from our excellent contemporary the *Scientific American*, deals with the subject in an exhaustive manner which is very interesting.]

The idea that anything can be added to light by passing it through coloured transparent substances, or by reflecting it from coloured surfaces, is utterly erroneous, and proceeds simply from ignorance of the nature of light. It has been proved by Isaac Newton, and since his time by innumerable experiments of various kinds, that pure white light, such as comes from the sun to us, contains all the colours, as well as heat and chemical activity, and that they may be separated, or the light analyzed, by simply passing it through a prism of a transparent substance. The possibility of such a separation has been understood only since the adoption of the vibratory theory, which also explains the nature of the caloric, luminous, coloured, and chemical rays. According to this theory, the vibrations, when at comparatively low velocity, manifest themselves as heat only; when the vibrations are rapid enough to produce four hundred and fifty billion waves per second they become visible as red light. Five hundred billions produce the sensation of orange, five hundred and fifty billions that of yellow, and so on through green, blue, and violet, the latter resulting from eight hundred and fifty billions of vibrations per second. Vibrations still more rapid are invisible to the human eye, but their existence is demonstrated by their chemical action, in the same way as the invisible vibrations below four hundred and fifty billions per second manifest themselves as heat only.

Densely transparent media retard the light, and this retardation will affect the rapid vibrations more than those of slower velocity; and under certain circumstances such media will cause light to be deflected from its course in such a way that the most rapid vibrations will be most deflected, and the slowest least. This is the principle of refraction, by which light can be separated into its caloric, chemical, and luminous rays of different colours. The refraction of light, permitting the examination of the colours into which it has been split up, is the fundamental principle of the spectroscope, by which the nature of various luminous and illuminated substances can be determined.

The apparent colours of objects are caused by their reflecting rays of vibrations of certain velocities, and neither reflecting nor absorbing others; and the hues of transparent coloured objects are similarly produced. They pass only certain rays, and absorb the others; and the reflected or transmitted colour is then called the colour of the object. In order to perceive such a hue, it is essential that the light by which it is illuminated contains that colour; and this is directly demonstrable by illuminating objects with

light of one colour, when objects of all other colours will appear black or grey. Such a light can, for instance, be produced by burning alcohol in which common salt has been mixed; this produces a pure yellow flame, and objects of whatever colour, when seen by daylight, if illuminated by such a flame, will only show this colour. Human faces, for instance, have in this light a ghastly, death-like appearance.

An ordinary gas, lamp, or candle light is not a pure white, being deficient in blue rays, and has an excess of red, orange, and yellow; a white object cannot, by such a light, be distinguished from a yellow one; light blue cannot be distinguished from green, and dark blue looks almost black.

In regard to the nature of coloured objects, whether painted or dyed, and of transparent media, such as coloured glass or liquid solutions, the analysis of their colours by means of the spectroscope shows that what we call simple colours are in most cases complex. Only those colours are pure and simple which we obtain by the prismatic refraction, namely, the spectroscopic colours. The blue cobalt glass, for instance, which is now called masarin glass, is proved by the spectroscope not to owe its violet shade to the very refrangible and chemically active violet rays at the extreme end of the prismatic spectrum; but, on the contrary, this part of the spectrum is totally absent from light passed through blue glass. The special shade of the masarin glass is caused by the fact that its blue is tempered by a considerable quantity of the less refrangible red rays at the other or caloric extremity of the spectrum, and even with a trace of orange. Its blue is, therefore, of less chemical activity than the prismatic blue, and of course in all its functions—such as heat, chemical action, &c.—is far below the original unchanged solar light.

We have gone into the details of these rather elementary matters for the purpose of exposing the ignorance of those who ascribe to the glass a special chemical or curative influence. Some photographers have used blue glass long ago, in order to moderate the intensity of the light for the eyes of the sitter, without robbing it of too much of its chemical activity; and those photographers who possess common sense or experience know that, far from adding to the effect of the light the blue glass is an impediment, and the necessary time of exposure is rather extended by its use than otherwise. It is strange that such errors can prevail for years, when a simple experiment can settle the matter. All that is necessary is to photograph the solar spectrum, to do the same with a surface painted with a number of various coloured pigments, and also to expose a sensitized surface under a series of coloured strips of glass. The writer of this article did this more than thirty years ago by the Daguerrean process, and satisfied himself about the following points: 1, The chemical effect of the prismatic spectrum extends, for iodide of silver, from beyond the violet to the blue; 2, When bromine is used in connection with the iodine, it extends to within the green, while the yellow and red rays appear to have no effect on silver compounds, but may possess it for other substances; 3, In photographing pigments there is the utmost diversity in the results, according to the nature of the pigment—much greater than the differences in shade would lead us to expect. As a general thing, the pure reds, orange, and yellow, such as are produced by vermilion and chromates of lead, are photographically inert, and give blacks. The blues are the most active; most of all being ultramarine, next the violet lakes. But even the red carmine takes well, as it has a violet shade; but among the blues, those bordering on green take least, and hence foliage tends to give dark effects, which are only slightly corrected by using bromine; 4, In using as negatives strips of coloured glass to print in sunlight, much depends on the shade and intensity of the colour. In general, the chemical effect follows the prismatic series from red to blue; but the most effective blue glass is always found to be far inferior to the sunlight alone, pure and simple. And this fact is sufficient to settle the question

readers will, I feel sure, be glad to learn something about it. M. Despaquis has observed, like all who have occupied themselves with this branch of study, that in an engraving it is necessary to have a grain inside the cavities, while the surface should be of a polished character in those portions destined to reproduce the whites of the image. He therefore set about to discover how such a result could be brought about. He applied to the metallic plate two films of gelatine, the first a thick one containing the grain, and the second thinner and absolutely free from grain. It is due to this second film that M. Despaquis is enabled to produce all the delicacy of half tone. His method of operating is as follows:—In one thousand cubic centimetres of water are dissolved two hundred grammes of gelatine; to this are added twenty grammes of liquid Indian ink and four grammes of powdered pumice, the latter being very finely ground and sifted through fine linen. Next, upon a plate of glass which has been waxed, he spreads a sheet of moistened paper, taking care to prevent the formation of air-bubbles. The solution of gelatine, previously filtered and maintained at a slightly warmed temperature sufficient to keep it liquid, is then poured upon this sheet of paper. In this way a sheet is secured, covered with a thick film of gelatine having a very fine grain, uniformly spread throughout its body. When it is desired to make use of this prepared paper the second film is applied, and the sheet sensitized at the same time; to do this, it is immersed (prepared side uppermost) in a solution composed of:—

Water	500 cub. cent.
Gelatine	1 to 15 grammes
Bichromate of ammonia	15 "

After remaining in this liquid for some seconds the sheet is taken out, and by two of its corners (still prepared side uppermost) it is drawn over a gelatinized plate, previously prepared with ox-gall, so that later the paper may be easily detached. The sheet, dried in a locality where it is screened from daylight, is cut a little larger than the cliché, and placed underneath the latter. The exposure of the prepared sheet to the light should be about a third that necessary to give a carbon print. As in this latter process, as soon as the printing is finished, the impression is placed into cold water, so as to transport the ink to the sensitized paper, but to a plate.

It is afterwards put ... 5 to 10 grains and finally the ... 1 ounce with weak strength of salt for line work, and I find, ... both solutions are diluted one-half, and No. 1 only allowed to change the tone of the deposit to grey, and not to bleach it, it answers well for half-tone negatives.

"The colour of the negative is changed to a deep red, and is very non-actinic. It should be flowed, while damp, with a solution of gum-arabic as a varnish."

HOW TO PHOTOGRAPH MICROSCOPIC OBJECTS

Dr. FAYET lately presented to the Academy of Sciences, Paris, the details of a new method of micro-photography. He placed upon a window sill the microscope he employs for the purpose, which had over the top a small wooden box supported on a tripod. This wooden box is the camera, which can be fitted and removed at pleasure, and has a plano-convex lens inside the camera, moved by a screw. By calculation the author had determined, first of all, and noted upon the exterior, the different heights that the camera should occupy in order to secure enlargements with the various powers employed, the image refracted by the lens being projected upon the focusing screen of the camera of the same size exactly as it is seen with the eye. Matters thus regulated, M. Fayet takes the microscopical preparation it is desired to enlarge, and reproduces and examines it under the microscope; and when the latter has been properly focussed, the camera is put in its place, without

* Philadelphia Photographer.

into all the various matters, and gives the most minute instructions concerning the operations involved, and informs the reader, moreover, of the methods for producing the different products necessary in the process. Especially does he tell about the pyroxyline and bromides, and clears up much about them which before was exceedingly obscure. With M. Chardon, collodion—or, in other words, the mixture of pyroxyline, alcohol, and ether—is simply a vehicle destined to contain the various active salts, which remain so far without any reaction upon one another. In the preparation of the emulsion, if the proportion of emulsion be insufficient, then the bromide of silver formed by the addition of nitrate of silver is precipitated in part, and the result is a granular film which has no strength of cohesion. If, on the contrary, the proportion of pyroxyline in the collodion be too great, the film which is formed will be too transparent, and display a lack of sensitive-ness. In this case the result will be clichés without vigour, which are incapable of being intensified. After numerous experiments M. Chardon has recognized the advantages possessed by a mixture of pyroxyline prepared one by immersion of the cotton in sulphuric acid and nitrate of potash (porous collodion), and the other by immersion in sulphuric and nitric acid with water added (resistant collodion). What distinguishes M. Chardon's work most of all is, however, the theoretical explanation, clearly and logically expressed, which he appends to his various practical results that are given.

A FEW REMARKS ON PHOTO-ZINCOGRAPHY

Proceedings of Societies.

PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

An ordinary meeting was held May 1st, President H. J. NEWTON in the chair.

The minutes of the last meeting were read, and, after some corrections by the President, approved.

The President introduced Mr. William Willis, Jan., of London, who exhibited a number of beautiful prints made by his

Platinum Printing Process.

Mr. WILLIS said: The object of this process is to produce photographic prints which shall be permanent (or unalterable) under all atmospheric conditions. This object is attained by the use of salts of platinum in such a manner that the finished image shall consist of this metal in the metallic state. Every chemist knows that metallic platinum is quite unaltered by any atmospheric influences, and is, moreover, unattacked by most chemical reagents; it therefore follows that prints produced in this metal are also permanent, and, to prove them so, they have been subjected to a great many severe oxidizing and other tests which have shown them to be impregnable. The process is founded on the following reaction. I discovered that platinum is instantly thrown down from its salts in a metallic state by a solution of ferrous oxalate in neutral oxalate of potash. Ferrous oxalate is a lemon yellow powder insoluble in water and in most other menstrua, its almost only solvent being the neutral oxalate of potash. Now it is well known that ferrous oxalate is produced by the action of light on

about the special virtues claimed for blue glass: it cannot possibly have any not already possessed by sunlight. However, if people are induced by its pretended curative properties to take sun baths, which they otherwise might neglect, they may be often benefited by the salubrious influence of the radiation of the mighty orb, an influence which cannot sufficiently be appreciated; but the blue glass would probably get the credit which exclusively belongs to glorious old Sol.

ON A NEGLECTED METHOD OF INTENSIFICATION.

BY J. CARBUTT.*

[REFERRING to a recent paper read before the Photographic Society by Captain Abney, on the "Copper Bromide Intensifier," Mr. Carbutt says:]

"This mode of intensification has been in use in this country for some years among those using negatives for photo-lithography and relief work; how long I do not know, or who is the author of it. I obtained it from a friend in 1874, since which time I have had it in constant use, but I do not think it has been used as strong as recommended by Captain Abney. Finding in my own practice that the use of a solution of nitrate of silver for blackening the whitened image was rather expensive, I sought to obtain a chemical reaction that should still be as effective without the expense, and the following extract from my notebook will explain it:

"February 19th, 1875. Important improvement in intensifying line negatives. The cupro-bromide solution given me by Mr. Walker I have modified by substituting a five to ten-grain solution Schlippe's salt for the silver solution used to blacken the film. I find a very thin negative only required. It gives the most satisfactory negatives for photo-lithography and relief-plate work I have ever obtained. It is most valuable.

"The formula is:

No. 1 Solution.			
Sulphate of copper...	400 grains
Bromide of ammonium	100 "
Water	20 ounces

No. 2 Solution.			
Schlippe's salt	5 to 10 grains
Water	1 ounce

The latter strength of salt for line work, and I find, when both solutions are diluted one-half, and No. 1 only allowed to change the tone of the deposit to grey, and not to bleach it, it answers well for half-tone negatives.

"The colour of the negative is changed to a deep red, and is very non-actinic. It should be flowed, while damp, with a solution of gum-arabic as a varnish."

HOW TO PHOTOGRAPH MICROSCOPIC OBJECTS

Dr. FAYEL lately presented to the Academy of Sciences, Paris, the details of a new method of micro-photography. He placed upon a window sill the microscope he employs for the purpose, which had over the top a small wooden box supported on a tripod. This wooden box is the camera, which can be fitted and removed at pleasure, and has a plano-convex lens inside the camera, moved by a screw. By calculation the author had determined, first of all, and noted upon the exterior, the different heights that the camera should occupy in order to secure enlargements with the various powers employed, the image refracted by the lens being projected upon the focussing screen of the camera of the same size exactly as it is seen with the eye. Matters thus regulated, M. Fayel takes the microscopical preparation it is desired to enlarge, and reproduces and examines it under the microscope; and when the latter has been properly focussed, the camera is put in its place, without

* Philadelphia Photographer.

touching either the microscope or the preparation, the eyepiece remaining in its place. He brings the lens down to the point corresponding to the scale referred to above, and, without even taking the trouble to look at the image upon the ground glass, he forthwith proceeds to put a sensitive plate into the apparatus. When the exposure is at an end, the cliché is developed in the ordinary way. The advantages claimed by Dr. Favel for this mode of operating are the following: 1. It furnishes to the physiologist the possibility of taking a photographic image of any object visible under the microscope, no matter to what scale it is enlarged; 2. It permits the production of an image without touching the microscope or the object or preparation under it—there is no need even to focus after the camera has been adjusted, because this is done automatically, and always remains the same; 3. It yields an image of the dimensions precisely of that seen through the eyepiece; and, finally, it allows one to transfer to a competent operator all the photographic labours connected with the affair. The microphotographs presented to the Academy of Sciences as the fruits of this apparatus were of a most interesting and remarkable character.—*Scientific American*.

Correspondence.

PHOTOGRAPHING BY LIGHTNING.

DEAR SIR,—On June 10th a severe thunderstorm visited Ramsgate; the lightning being very vivid I tried to obtain a photograph, and succeeded perfectly after sensitizing a quarter-plate in the ordinary way. I placed it at the back of a negative. Four flashes were counted, and upon developing up came the image as clear and as quick as if taken by ordinary daylight. One flash with a weak negative gave a fair transparency. I next tried with the camera; after getting everything nicely in focus through my studio window, which was done by the aid of lightning, I obtained a photograph with twenty flashes, the view being the back of Queen Street, Ramsgate. This, I think, shows most clearly that the chemical power of lightning is quite equal to the electric light produced artificially, and nearly equal to daylight. As this is the first time I have ever heard of a photograph being taken by lightning, I thought it worth communicating to the PHOTOGRAPHIC NEWS.—Yours truly,

A. J. JARMAN.

Proceedings of Societies.

PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

An ordinary meeting was held May 1st, President H. J. NEWTON in the chair.

The minutes of the last meeting were read, and, after some corrections by the President, approved.

The President introduced Mr. William Willis, Jun., of London, who exhibited a number of beautiful prints made by his

Platinum Printing Process.

Mr. WILLIS said: The object of this process is to produce photographic prints which shall be permanent (or unalterable) under all atmospheric conditions. This object is attained by the use of salts of platinum in such a manner that the finished image shall consist of this metal in the metallic state. Every chemist knows that metallic platinum is quite unaltered by any atmospheric influences, and is, moreover, unattacked by most chemical reagents; it therefore follows that prints produced in this metal are also permanent, and, to prove them so, they have been subjected to a great many severe oxidizing and other tests which have shown them to be impregnable. The process is founded on the following reaction. I discovered that platinum is instantly thrown down from its salts in a metallic state by a solution of ferrous oxalate in neutral oxalate of potash. Ferrous oxalate is a lemon yellow powder insoluble in water and in most other menstrua, its almost only solvent being the neutral oxalate of potash. Now it is well known that ferrous oxalate is produced by the action of light on

ferric oxalate; if, then, a piece of paper be coated with this latter salt and exposed to light under a negative, we get a faint picture in which the parts affected by light consist of ferrous oxalate. In my process the paper is coated with a salt of platinum in addition to ferric oxalate. If paper so coated be exposed to light under a negative, we shall have, as before described, a picture in which the parts acted on have been changed from ferric to ferrous oxalate; but in this case the picture in ferrous oxalate is in contact with the salt of platinum, with which the paper is also coated. In this state no reduction takes place in the platinum salt, because the ferrous oxalate in contact with it is not in solution. The moment, however, this faint picture is floated on a warm solution of the neutral oxalate of potash the ferrous oxalate is dissolved, and in the instant of solution reduces the salt of platinum in contact with it, and so forms the picture. This is merely an outline of the general principle on which the process is founded; but to make a practical use of it requires experience and familiarity with the different manipulations. In conclusion, I may mention that the exposure to light required by this process has been variously estimated at from one-fourth to one-sixth of that required in the ordinary silver printing process.

The PRESIDENT inquired if a picture that was over-exposed could be remedied when developing.

Mr. WILLIS replied that it could not, as it is then fixed, and cannot be altered. But he had not yet found any trouble from that cause, as very little practice would enable a person to judge of the correct time for exposure.

Prof. C. A. SEKLEY remarked that this process of Mr. Willis was certainly deserving the attention of photographers.

The PRESIDENT said that the specimens exhibited were very beautiful, and from the description of the process the natural inference would be that they were permanent. He hoped that this process would be fairly tried by the photographic fraternity.

Emulsion Portrait Negatives.

The PRESIDENT said that some time since he stated that from certain indications he was satisfied that emulsion could be made practical for portraiture in the gallery. Hence he had been experimenting in that direction for the last twelve months, and had so far succeeded that he felt justified in stating that he could make better negatives with less exposure and with greater certainty of results than could be made by the ordinary bath process. For gallery work he used the emulsion wet, simply washing the coated plates with water until the greasy lines disappeared. An ordinary glass bath-holder filled with water was very convenient for this purpose, for in this the plates might remain any length of time, suiting the convenience of the operator, without fear of injuring the working qualities of the emulsion.

The PRESIDENT then exhibited a number of portraits made with emulsion with an exposure of only one-third the time of his ordinary bath process. These pictures seemed to call forth not only surprise, but universal commendation. They were, in fact, pronounced the best emulsion work ever exhibited before the Section, and quite equal to the capabilities of any process whatever.

After the examination of the pictures by the members, the PRESIDENT stated that he had not yet published the formula by which these were made, but expected to at some future time. For the present he preferred to have the making of the emulsion under his own supervision and control, not because he desired to make money by withholding it, but to protect himself from adverse criticism; for he had noticed that a published formula was rarely followed strictly by those who attempted to use it, and the failures thus resulting were unjustly attributed to the process. M. Laudi, of Columbia College, says in a letter to me a few days ago—"Your wet emulsion plates I find develop readily with an exposure of one-half the time of bath plates, and with far better results. I do not, therefore, hesitate to state that your emulsion process is entirely practical, and it must and soon will be adopted by all who will give it a trial."

Prof. CHARLES A. SEKLEY said that he remembered this emulsion process some seventeen years ago, just as he was stepping out of photography. The emulsion then had an excess of silver, so it would not keep long. It was slow, and the collodion would deteriorate, though he remembered some very fair pictures were made with it. But the process was uncertain. The present method of the President he considered a perfect success. Looking at it from the standpoint of seventeen years ago he would say it was perfection, and, as far as his judgment went, he would be much surprised if it did not come into general use.

Mr. D. C. CHAPMAN exhibited two negatives, and said he supposed they were all aware that his work was principally for astronomical purposes, and hence it requires chemicals as sensi-

tive as possible; and in order to get the maximum amount of sensitiveness from wet iodide of silver plates, he gave them a pre-exposure to light, which increases their sensitiveness about three-fold. In making some experiments with emulsions, both dry and wet, he tried the pre-exposure, to see if the same increase of sensitiveness could be obtained by that method, or, in other words, to see if a pre-exposure would affect the bromide of silver in the same manner as it does the iodide. He had brought with him two negatives which he had taken, one with the dry emulsion, and the other with the wet. One-half of each negative was exposed to light previous to being exposed in the camera, and he failed to detect any difference in the sensitiveness of the sides when being developed, as the negatives which he exhibited would show. He was therefore under the impression that the sensitiveness that can be obtained from an emulsion plate must be derived from the chemicals rather than by any pre-exposure.

Mr. T. C. ROOZE said that any good emulsion could be made to work more rapidly by first washing the coated plate thoroughly with water, and then flowing over it a solution of alkaline albuminate of silver before exposure. This solution is made by using the white of one egg, two ounces of water, and a few drops of aqua ammonia. To this is added enough of a thirty-grain solution of nitrate of silver to make the mixture milky. Now add ammonia again until the solution becomes clear. A few drops will be found quite sufficient to accomplish this. Before development the plate should be well washed, and a ten-grain solution of bromide of potassium flowed over; then wash and flow on the pyro. The picture will show up quickly. Now add a few drops of ammonia and bromide of potassium solution to the pyro, and complete the development.

Talk in the Studio.

HELIOTYPE PRINTING.—From a circular issued by Messrs. B. J. Edwards and Co. we learn that a rumour to the effect that they were giving up business as photo-mechanical printers is without foundation. Mr. B. J. Edwards leaves the firm, which will be carried on in future as H. M. Wright and Co.

DISPUTED LIKENESS IN A PORTRAIT.—"Miss Helen Barry," *The Theatre* remarks, "is not a lady to be trifled with. Mr. Gilbert Dickenson, of Bond Street, had received a commission to paint for thirty guineas a portrait of her in the character of Princess Aouda in 'Round the World in Eighty Days.' He executed the order, but when the portrait was delivered the lady refused to take it in, on the ground that it was not at all like her. Mr. Dickenson said that the lady had failed to keep several appointments for a sitting, and that the picture had had to be finished by the aid of photographs alone. 'True,' said Miss Barry, 'but I was unable through illness to come; and this you knew.' Mr. Dickenson brought an action against Miss Barry in the Bloomsbury County Court for the sum referred to, and the judge, without calling upon her counsel, gave a verdict for the defendant; a decision from which there is to be an appeal. Mr. Montague Williams, who appeared on her behalf, seems as quick as ever to seize a point. 'Is the lady in court?' asked Mr. Dickenson's counsel. 'She is,' replied Mr. Williams; 'but as you suppose that that painting resembles her, I am not surprised at your failing to recognise her.'"

HOAXING A PHOTOGRAPHER.—The race of practical jokers is not extinct. There are still men whose love of fun appears to be stronger even than their love of money. They have their joke, and they do not grumble over-much to pay for it. It may be that they occasionally pay too dear for their whistle; but what is money, after all, compared to the gratification of the passion animating your practical joker? Such men risk friendship as well as money; and it has happened in the case under notice that the joker has lost his friend as well as his cash. It would be impudent to mention names in this affair—vulgar curiosity must find them out for itself. I may help the curious, however, by stating that the records of the County Court would furnish all the information they desire on this subject. It appears, then, that a few weeks back a certain well-known veterinary surgeon sent a pressing message to an equally popular photographic artist with regard to a horse then lying in *extremis* at Kingwinford. The horse was dying, and the desponding owner desired to have his picture taken before it was too late. Besides, it was possible that the likeness would be required in a County Court action, inasmuch as the

animal was dying from injuries received in a collision. The photographic artist obeyed this order with his usual alacrity. Cruel to relate, however, he found, on arriving at Kingswinford, that there had been no accident, that no horse was dying there, and that the owner contemplated no action in the County Court. That action was reserved for the disappointed artist himself. Though one of the best tempered men in the world he did not see the justice or the fun of sending him and his artistic paraphernalia on a bootless errand of this kind; and so, while his friend the "vet." was rampant with delight, the artist quietly put him in the County Court for three guineas! The money has since been paid, without the formality of a trial before Judge Kettle, and the event is being commemorated by the issue of a picture, not of a dead horse, but of three sovereigns and three shillings artistically arranged as "an allegory."—*Dudley Herald*.

PAINT BURNISHING.—Rub over your prints and mounts, before burnishing them, the following solution. It keeps out moisture from the prints, and preserves them, and gives a brilliant finish far superior to any soap or soap solution, which absorbs moisture, and soon injures the picture. Take white wax one hundred and twenty grains, ether two ounces, alcohol sixteen ounces. Cut or scrape the wax fine, and add it to the ether; shake, and it will soon dissolve; then add the alcohol, and shake well again to mix.

To Correspondents.

PETER SNAWCROSS.—The simplest mode of dealing with used developing and intensifying solutions is to add them to used hypo solution.

NEMO.—The size of a skylight for printing under must depend entirely upon your facilities as to space, &c. We should think about thirty feet long and six feet wide would answer, the skylight being of the lean-to form. If the tables on which the printing-frames are placed are made with large, easy-running castors, they can be readily pushed into the open, or withdrawn under the skylight, as may be required.

CONSTANT READER. must be aware that we have given many hints on the subject of blisters in prints. Many plans have been proposed, but none have proved universally successful, especially when very highly albumenized paper is used. The addition of alcohol to the hypo bath has been found often successful. Placing the prints in salt and water instead of plain water when they leave the fixing bath has been found useful by some. When they occur, change the first washing water, and then the second. There is a tendency in the blisters to turn black.

J. J. WALKER.—The risk of the printing breaking up is reduced by making it as thin as possible. The object of the mixture of nitric acid and spirit is to coagulate the albumen in the film, as well as to remove the bichromate, and the stronger the spirit, the better it will perform its work. The resin which is added to methylated spirit to constitute it "finest" is usually shellac.

THOMAS WHITE.—We should be disposed to refer the defect to some impurity in the washing water. You are fortunate, however, in having the remedy you mention. Avoid, in future, working in the room where the defects occur.

W. W.—We do not remember the address. We very rarely use alcohol in the developer at all, and we think it much better to avoid it. If added, it is better done at the time of use. Acetic ether is at times formed in a developer containing acetic acid and alcohol. But the special defect you mention is not likely to arise, as ether will not act on the wet film.

G. WALTER.—The difficulty arises from the slight solubility of the potassium salts in highly rectified alcohol. The best remedy is to grind the salts in a mortar with a few drops of water, and then add alcohol, and grind again until the whole is dissolved. When adding to the collodion, add a little at a time, and shake well between.

YOUNG PRINTER.—It is always wise to have a stock of toning solution ready for use; but it is not difficult to prepare a solution which may be used in a few minutes. When this is necessary, take of your stock solution of chloride of gold as much as contains one grain. Make this into the condition of thick cream by rubbing up with it prepared chalk. Now pour upon it six ounces of hot water, and stir well. As soon as the solution is cool, it may be used, and will be found to tone satisfactorily. It is always wise to make the tub of gold containing fifteen grains into solution with fifteen drachms of alcohol, each drachm then containing one grain of chloride of gold. It is less liable to reduction in alcohol than in water.

A. F. SMITH.—Thanks for charming prints and fine cloud negatives. We shall have something to say on the subject in our next.

B. F.—The pyroxyline is bad. It is very insoluble man fatty from your account of it, and three grains to the ounce of solvents gives a glutinous collodion. Pyroxyline to yield good collodion should, as a rule, dissolve freely at the rate of four or five grains per ounce in equal portions of ether and alcohol, and this should give a lumped collodion flowing freely, and giving a good film. We believe Mr. Atkinson, of Liverpool, keeps Anthony's cotton.

H. M. K.—The prints have not arrived.

W. COLQUHOUN.—We cannot explain the delay. It probably arises from the firm in question having more limited facilities for carbon printing than the other class of work. We regret that we do not see any way in which we can help you. There is no doubt about the respectability of the firm, although the case you describe seems to indicate imperfect business arrangements.

R. & J. W. B.—It has been held of late, in relation to literary copyright, that registration is only necessary preliminary to commencing an action for infringement. Our understanding of the Fine Art Copyright Act is, however, that registration is necessary before suing prints.

H. N. WHITE.—We regret to hear of the negligence in relation to your letters, which should have been answered by the gentleman to whom they were addressed.

J. H. WHITBROOK.—Many thanks. We shall have pleasure in publishing your remarks in our next.

W. W. WINTAN.—The matter shall have our consideration. Several Correspondents in our next.

METHEOROLOGICAL REPORT FOR MAY.

BY WILLIAM HENRY WATSON, F.R.S., F.M.S.

Observations taken at Braystones, near Whitehaven, 36 feet above sea-level.

PHOTOGRAPHY IN AND OUT OF THE STUDIO. PLAYING AT PHOTOGRAPHY—STEIN AND KÖNIG SOUND EXPERIMENTS.

Playing at Photography.—Every day does the army of amateur photographers receive acquisitions of strength. Indeed in this country we should not be surprised if the amount of apparatus and stores employed by ladies and gentlemen who occupy their spare hours in practising the "black art" does not far exceed that made use of by professional photographers. The progress in landscape photography made by us is in a great measure due to the exertions of amateurs, who number in their ranks artists quite as competent as the best professionals. Again, in the domain of portraiture, with such a bold and daring amateur as Mr. Crawshaw, of Cysartliffa Castle, at their head, the dilettanti portraitists of Great Britain are not to be despised, but now and again produce work which takes a deal of beating. In fact, in any exhibition of photographic work, it is quite impossible now-a-days to observe any difference between the pictures of the professional and amateur element, since the exhibitors in both cases usually number among them very capable photographers. At the same time, it is well that those ladies and gentlemen who are desirous of taking up photography as a pastime should well understand what they contemplate. It is not sufficient to purchase a camera and a collection of chemicals to produce the bijou landscapes of a Russell Manners Gordon, or the bold finely-conceived studies of a Crawshaw. When you have bought a mowing-machine, there is still the lawn to cut, and this is not to be done by looking on, as many a young gardener has found out to his cost. The would-be photographer observes how easy it is to focus and develop a plate, and as it is only a matter, apparently, of possessing a dark room and a stock of apparatus and chemicals, there is no reason, he thinks, why he should not throw himself at once into the very middle of the thing, since he has money enough to acquire the requisites. He may, if he has enquired, hear something of the disagreeables of the nitrate bath, but these vanish from his mind at once as he hears of emulsion plates which require no bath at all, or the singularly ingenious apparatus of M. Warnerke, of which, so he has heard, you have merely to turn the handle to get as many nice pictures as you want. The misguided youth is on the brink of embarking upon that mysterious voyage of alkaline development before he has learnt even to know the vessel that carries him. As well tell a captain he need know nothing of navigation, since his ship will be propelled by steam. To hear some people, neither a knowledge of the principles of art or science are requisite to the practice of photography since the improvements that have recently been made. Nay, one need not even have recourse to a dry plate process to secure photographs in a free and easy manner. You may purchase an apparatus having attached a series of bulbs and elaborate contrivances, and without touching liquids or weighing out a lot of corrosive substances, you have merely to work away mechanically, pressing a bulb here, screwing a winch there, and adjusting a button or two, to obtain your picture. Perhaps you may be diffident about the apparatus producing a good photograph, but on this score your mind is soon set at rest, for a series of excellent views are exhibited all emanating from a similar machine with a man at the end of it. But then the man may not have been the duffer you yourself will prove when you once begin to work and find yourself, after some exercise of mind, of wiser, if of sadder disposition. What man has done, man can do, is a very good precept, and one that looks exceedingly well in a fine Italian hand at the top of a copybook. But in photography, as in most other things, this qualification of itself is not sufficient to command success. We know there are many

who would have young people believe that there is nothing so easy as photography, only you must buy their lens or their peculiarly prepared patent actinic bromo-chloroformed pellicle, the exposure of which is only half that of wet collodion plates, while the results are ten times as good. And here we may put in a word of advice to amateurs not to be misled by the beauty of results which are produced by this or that plate or one or other patent lens. One of these days we shall have a manufacturer of hyposulphite of soda sending round specimens, magnificent portraits and landscapes, to show how nicely his fixing agent works, and what pictures those photographers who employ it are capable of securing. No doubt, proofs and specimens are worth looking at in a fashion by those thoroughly initiated, who can form some idea of the depth of focus of an instrument, or of the tone and texture of a paper; but with amateurs, who have little experience in such matters, a photograph teaches little or nothing, and, on the whole, is rather liable to mislead than anything else. For all this, we would not dissuade ladies and gentlemen from taking up our charming art. Those who will give the subject their earnest attention, and steadily resolve not only to learn by precept but by practice, will produce something more than mediocre photographs. There are several ladies of our acquaintance who are very competent photographers—some, indeed, who in their own branch are not to be beaten—but then they have not adopted photography for the purpose of gratifying a passing whim, but in order to prosecute an art with which they could feel some sympathy. Mrs. Bramey, who recently accompanied her husband round the world in the yacht *Sunbeam*, is said to be an accomplished photographer, and to have used her taste and skill to some purpose during her long and chequered voyage; Mrs. Julia Cameron, as everybody knows, has executed several works of note; and the names of other ladies might also be mentioned, taken from the catalogues of exhibitions, who rank almost in the first line of photographers. The art is, indeed, eminently suited to those with a taste for art and sufficiently earnest of purpose to prosecute their work seriously. To those, however, whose only desire is to amuse themselves for an hour or two now and then, we would say, Try something else. Photography does not mean purchasing a packet of papers with directions, and messing about with a few acids and guano, as most schoolboys think; neither can it be pursued by acquiring a doll's set of apparatus like a child's tool-box. If you have neither time nor inclination, your efforts will simply end in spoiling your clothes and losing your temper.

Stein and König's Sound Experiments.—Dr. Stein seems to have succeeded in photographing records of the human voice in the same way as he previously managed to photograph the tones of the violin. In the latter case he cut a little disk astride one of the strings, and when the latter vibrated the disk naturally vibrated too. A hole in the disk permitted a pencil of light to fall upon a moving sensitive plate; and in this way a curved line was secured, the ups and downs of which were as frequent as the vibrations. M. König, who has also been making experiments of late with a view to securing pictorial records of sound, proceeds to get his pictures in a different way to Dr. Stein. He employs a sensitive or singing flame for the purpose, the shape of the latter being influenced by vibrations set up in the atmosphere, either by a musical instrument or the human voice. But we do not think that M. König has yet been able to secure photographic records of the flame forms he thus produces.

THE BACKGROUND.

BY G. E. SWAIN.*

In a busy picture career of more than a quarter of a century, a devotee with even ordinary observation must necessarily see many things interesting, and some worth com-

* *St. Louis Practical Photographer.*

municating. It does not do to be always patting each other on the back, and congratulating ourselves on the progress of our art, and the giant strides, &c., made in our glorious, yet occult, profession; for to thoroughly put our houses in order would make our stormy days for a long time to come very busy ones indeed. There is a plentiful lack of real artistic knowledge yet in the craft—or, as some will style it, the trade—which if we all mutually help to sweep away with modesty and honesty, and without ostentation, we may at some future period (say fifteen million years hence) be able to notice a marked improvement. Some people may be unreasonable enough to object to waiting so long for the desired result. Now, all such persons I would politely refer to Professor Darwin, Huxley, or Tyndall, either of which astute gentlemen will cheerfully reconcile their patience or impatience, just as they please, by telling them that that is a mere atom of time compared to the eras necessary to thoroughly develop the doctrine of evolution—with which consoling information let us continue our little lucubration without any further prologue, although a due sense of the amenities of modern journalism justifies your humble correspondent in making this rather windy introduction on making his bow to the high-minded, the enlightened, and intelligent readers of *The St. Louis Practical Photographer*.

I have often heard it said that one volunteer is worth two pressed men, and, with a determination not to be always kept in the background, I timidly step forward with my first-born contribution to your worthy journal, on that all-important yet painfully-neglected subject, "The Background." I know many very excellent sun-painters, men who are almost morbidly conscientious in everything they undertake; who run wild about the aspect of their skylight, scrupulously particular about its pitch, height, top, bottom and sides, who become frantic with joy over the questionable success of some new patent collodion; spend the term of half their natural lives in looking for or sighing after a good lens; have experimented on every formula that has ever been patented, published, thought, or dreamed about by the most visionary silver fiend, and possessing an operating-room full of gaudy furniture, rich satin curtains, miscellaneous draperies, some of them very imposing, some very shabby (and all very dirty), where you may see birds, bells, whistles, and fiddles to gammon the children; and one enterprising friend of mine actually has a handsome musical box, which strikes up "Smile as thou were wont to smile!" the moment he removes the camera cloth, and yet, marvellous to state, not a good, competent, practical nor appropriate background! Now, most sun limners imagine that with possession of the aforesaid paraphernalia that their atelier is complete, for, they say, with apparent conviction: Have I not my background, and very dark one; also my "Circumwizzle double-back-action-rotary Rembrandt vignette affector," and my fancy interior, and my picturesque exterior; to say nothing of my Corinthian and Gothic columns, in themselves quite a plethora of resources; in fact, prepared for any emergency—a sort of invulnerable artistic Ajax, armed at all points *cap-a-pie*. While talking to one of these brilliant lights of our profession, the other day, a beautiful little blonde miss, all in white, tripped in to be executed. Our friend at once rushed to business, and as the traditional chair was there in that familiar spot, and had been for the past "decade" (a fact easily attested by the threadbare-appearance of the carpet within a radius of "two feet"), he gave it a twist (the chair, I mean, and not the carpet), and in his hasty opinion every necessary requirement was fulfilled. I should state that the background that was doing duty at that moment happened to be the dark one, and, to my horror and amazement, was allowed to remain there, not at all by inadvertence, but by choice, as I was solemnly told that the contrast would give wonderful strength, and a very stunning effect. Well,

it did, and the stunning began with me. Such a picture could be nothing else but a chalky hobgoblin.

Next came an old couple to tax the resources of our model operating-room, and, like all loving couples, they desired their pictures to look at or towards each other. Here our Knight of the Tripod was in somewhat of a quandary; both of the old people having pale blue eyes, almost the colour of grocery milk, neither could very well face the light. A Rembrandt effect on one and not on the other might be productive of much unfavourable criticism on delivering the pictures. Turning the negative when making the print cannot well be done, so there was no alternative but to sit one of the twain on the other side of the room; and then began such pulling and hauling of scenes, and a scrunching and squealing of rollers, and the headrest nearly inserted itself twice into the picturesque exterior before our artist settled himself to work again. I saw a troubled expression on his usually happy face, and easily divined the cause. The fact is, that his light never did work well on that side of the room—*forsooth*, as if any skylight ought to exist that you cannot work with equal effect and facility, no matter from which side of the room; and I venture to say that any one who has a skylight that cannot be so worked is like a one-armed soldier, and left-handed at that, for with the choicest instruments, the purest chemicals, and the daintiest manipulation, your success can only be comparative without the proper light.

Now, just to have so is not the purpose of this modest little article; and this reminds us that we started with the intention of saying something about backgrounds, so *revenons a nos moutons*, or back to our backgrounds, in good Saxon. If I am ever unfortunate enough to own a gallery, I'll develop a little plan of my own for a background that I have given much thought to, yet, strange, I have never communicated to any one—*i.e.*, to have my background in the shape of a small panorama, and to work like one, I mean, but in a more simple manner, on two vertical rollers, and the ground working horizontally backwards and forwards in size—say, about eight feet high by fifteen, twenty, or thirty feet long—beginning with a perfectly plain tint and a very light shade of grey, and imperceptibly descending to a darker grey, but by no means very dark, as I think that very dark grounds are about as bad as long sermons—an abomination—and instead, as some contend, of throwing out or relieving a picture, absolutely kill it. This is more especially the case in vignette pictures. I should take care that the dark end of my ground would graduate from the light, so that the sitter would always have the background an infinitesimal shade darker on his light side than on his shadow side. By one or two turns of the roller you can have any degree of ground to exactly suit your subject in either his costume or his complexion. Many vainly try to obtain this end by manoeuvring the clumsy grounds they have, but all to no purpose. Very rarely, indeed, are they successful; whereas, with this accessory you might give a wide berth to the artistic interior and the picturesque exterior, and, as for the circumwizzle, delegate it to the nearest junk shop, where it properly belongs. Bear in mind, I am neither peddling nor puffing any crazy patent. Having read and inwardly digested the remarkable prospectus of our worthy Editor, I reverence and respect both, and govern myself accordingly. All I wish to do is merely to ventilate what may appear a crude idea, which may fall as harmlessly as a snowflake in the river, or it may unexpectedly germinate, blossom and ripen in the fulness of time, all to the honour and pleasure (but not profit) of the obscure and blushing writer. I know it is difficult to uproot old customs. Ruts are hard things to get out of. Only fifty years ago the most cultivated and civilized people in the world—the French—cut their hay and corn with a sickle. Fancy stooping at that work all day, as they used to do, from 4 a.m. to 7 or 8 p.m., with only a few minutes' interval, cutting only just a mere handful at a time! And would

you believe that it took many, many years to introduce to them the now old-fashioned scythe, with which they could work standing erect in a natural position, and with one sweep fell twenty times the quantity; and at this day they stoutly ignore most of our labour-saving, new-fangled Yankee agricultural improvements.

If I were out of business (which, happily, I am not), and prospecting around for a likely thing to embark in, I should at once commence the manufacturing of these backgrounds. I have probably not, nor have I tried hard to make myself sufficiently understood in this paper to answer to any one for a working plan or model; but should any individual be bold enough to enter on this new industry, the writer would cheerfully give him all the necessary details free gratis for nothing.

In closing these remarks, he would say that he claims to be no prophet nor reformer, and would not so be "counted in" on any ticket; nor does he consider himself "a wise man from the East," but simply desirous to awaken a keener interest on a subject to which too much importance can never be attached, and one, alas! that can very easily be neglected.

On these grounds alone (no pun intended) our good and worthy editorial Cerebus may with safety give a corner of his valuable space in furtherance of a motive at once so laudable and disinterested.

HOW TO SHORTEN EXPOSURES.

BY GUSTAV WEHL.*

How general is the interest felt in this subject may be gathered from the circumstance that the Photographic Society of Vienna has offered a prize for any method that shall materially curtail the ordinary periods of exposure; while, if further proof were wanting, it is to be found in the fact that photographers are always willing to listen to any means which has the same end in view. A short exposure is for many reasons to be valued, and one of the most important of these is the fact that it multiplies the chances of getting a good picture, for it enables one to seize the proper expression at the right moment in a portrait, and also to secure a natural look or smile which is only possible in the case of brief exposures. How many times do we hear the complaint that the expression in a portrait is not a happy one, or that the proper expression has not been caught at all. Hence the shortening of exposures must always remain one of the principal aims of the portrait photographer. Whether it is possible to shorten further the exposure of a plate by increasing sensitiveness of our chemicals is a point I will not here discuss; but it seems to me that optics and the technical treatment of the subject are more likely to help us in our endeavour.

The proposition made some time ago to expose the plate to light after it has received an impression of the object was a step in the right direction, but it was a method of little use, since the light impressed upon the plate in this way covered the shadows, and therefore weakened these latter in the picture. The after-exposure of the plate must, before everything, permit of the gradations of light and shade to continue in their true relation, if it is to be of any real value. This I am enabled to bring about by changing the diaphragms during exposure. Without a diaphragm, and therefore with a full aperture of the lens, no practical photographer will care to work, unless he does not care to obtain sharp and harmonious pictures; for this reason it is customary to work with a second, third, or fourth diaphragm, as the case may be. If, however, a diaphragm of this kind is momentarily withdrawn before the exposure is complete, it becomes possible to shorten the exposure by about one-third, without in the least interfering with the gradation of the tones in the picture. An exposure of twenty seconds may very easily be reduced to

twelve or fifteen, and in this case the image obtained by the shorter exposure will be preferable, if the latter is so arranged that for a period of nine to ten seconds the plate is exposed with a diaphragm, and during the last three seconds this is withdrawn. To make the picture quite successful it is only necessary that the withdrawal of the diaphragm should be quick and certain, so that the lens sustains no shaking during the process. To do this I have arranged my lens so that by pressing a spring under it I can at once withdraw the lens without attracting the attention of the sitter or permitting the camera to be shaken.

When it is necessary to work with very small diaphragms, or to have recourse to very large lenses of four, five, or six inches diameter, in which case an exposure of one to two minutes is necessary, then the proportion of shortening the exposure is larger still. As a rule the time of exposure may be so divided; three-quarters of it with diaphragm, and one quarter without. This proportion not only permits one to give a shorter exposure, but the image produced possesses much more harmony in its details and gradations than would be the case if the diaphragm remained in the lens during the whole period. Experience will, however, soon teach the proportion which the first portion of the exposure should bear to the second, but it is well to bear in mind that in the case of short exposures (from ten to twenty-five seconds) the after-exposure should never exceed one-fourth of the whole duration, while in the case of longer exposures it may be set down at one-sixth. The following table may be of use:

Exposure under ordinary circumstances.	Shortened Exposure.		Total.
	Preliminary Exposure.	After Exposure.	
15 seconds	7 seconds	2 seconds or $\frac{1}{2}$	9 secs.
42 "	18 "	6 " or $\frac{1}{4}$	24 "
1 min. 12 "	28 "	7 " or $\frac{1}{5}$	35 "
2 " 24 "	50 "	10 " or $\frac{1}{6}$	1 min.
1 hour	32 min.	3 min. or $\frac{1}{20}$	35 min.

In this table I presume that the third and fourth diaphragms are made use of.

THE PRODUCTION OF NEGATIVES SUITABLE FOR PRINTING IN NATURAL COLOURS.

BY LEON VIDAL.*

WHILE prizes are being offered for various improvements in photographic science, it appears to be an opportune moment just now to call attention to the immense interest which attaches to a method of executing clichés which are capable of reproducing objects in all their relative value. This question is one of the most important of our art, and we do not wish to see it neglected for other matters, no doubt interesting in their way, but of less importance.

Although it is possible to secure very perfect results in a photograph, it is well known that the least negligence or the omission of one detail or another in the manipulations militates against the production of a perfect image. The cliché or negative is no doubt the principle upon which everything else depends; if it is bad, or if it is inexact, so far as regards the relative value of the tints and tones of the object reproduced, it is impossible to get a satisfactory image. Now, with the exception of grey or black engravings and monotone sketches, there is always the difficulty in photography of having to reproduce various colours. In taking landscapes, in which the greens and the yellows are not too vigorous, their luminous value is not readily reproduced, and the same may be said of the yellows, the reds, the greens, and the browns

* *Photographisches Correspondenz.*

* *Moniteur de la Photographie.*

in a picture, which are not reproduced upon the negative in their relative value.

This effect or cause of error is known to everybody, and it seems to us only right that some means should be taken to combat the defect, and to encourage those who occupy themselves with its destruction.

In our opinion this is a most important point to study, for at present one may well accuse photography of falsifying all the tones. It is necessary that we should be able to prepare sensitive films whose impressionability should be the same under the influence of all rays which are reflected, no matter what their colour is; or that we should have it in our power to place in the path of the reflected rays and between them and the sensitive film (before the lens) a translucent substance endowed with the property of identifying the simultaneous action of every one of the rays irrespective of its colour.

The idea of M. Ducos du Hauron, applied not to the formation of three distinct clichés, but to one sole negative, indicates the manner in which the solution of the problem might be arrived at. In this case it would be necessary to have before the lens a disc formed of segments of coloured glass, the one green, another blue, and a third orange, and the surface should be in proportion to the different periods of exposure which would be necessary for the preparation of three distinct clichés with the various glasses. The disc would be provided with an arrangement to give it a rotatory motion.

A cliché produced in this way should produce the same effect as one taken from a picture in grey monotone. The method might be somewhat impracticable for animate objects, but might well be tried of still objects. We only cite it in order to illustrate our idea more fully. It would be possible also, no doubt, either by varying the nature of the product introduced into the sensitive medium, or by modifying the development, to bring about the result desired.

We are of opinion that the establishment of a prize to be awarded for the best process which leads in the direction of securing clichés of relative value to the objects photographed will be productive of much good, and induce investigators to bend their steps towards this goal; and we believe that we are rendering a service to photography in invoking attention to such a subject of all those desirous of enriching the art with a new and precious discovery.

ARCHÆOLOGY AND PHOTOGRAPHY.*

THE second volume of the late Lord Dunraven's "Notes on Irish Architecture" has now appeared, and the work is thus completed. The book cannot be called light reading, but it is a careful and trustworthy record of extremely interesting and valuable remains which every year are likely to become more mysterious by the transformations of time. The ivy-grown towers and ruined arches, rough cairns, and circles of uncemented stones, which are the existing monuments of early architecture in Ireland, are minutely described in Lord Dunraven's work, and the assistance of the autotype process of permanent photography has been called in to place the picturesque ruins before the reader with peculiar reality and beauty. The work was left in a fragmentary state by Lord Dunraven, but has found in Miss Stokes an editor of considerable attainments and judgment. Her appendix on the vexed question of the Round Towers of Ireland is a remarkably clear and persuasive, if not exhaustive, statement. Professing to give Lord Dunraven's views as well as her own upon the subject of the weather-beaten towers which astonish the wayfarer in desolate villages and on remote hill-sides in many parts of Ireland, she arrives at the conclusion that they were built in the years between the close

of the ninth century and the middle of the thirteenth, as places of refuge for the ecclesiastics in times when the Northmen were ravaging the coast and making their way inland, and when the native Irish themselves had lost their ancient awe of the sanctity of the church. Bells were afterwards hung in them, like the silver bell, of wonderful sweetness, which once swayed in the Rattoo, and which, after it was thrown into the river Brick to keep it from the enemy, the peasants used to hear, or thought they heard, sounding its melancholy note beneath the water. All theories of the pre-Christian origin of the towers are summarily dismissed, and the round belfries of San Giovanni Battista in Ravenna, Dinkelsbühl in Bavaria, &c., are compared with the more isolated towers which long have been the favourite subject of discussion among those interested in early Irish architecture. A list of one hundred and eighteen round towers in Ireland, and of twenty-two abroad, is given, and a map is added to show that in Ireland the towers were placed on those coasts and rivers which were chiefly infested by the Scandinavian pirates. The book, however, must not be supposed to be devoted exclusively to the round towers. The owner of the beautiful manor of Adare, rich in ruined cloisters, the companion of Montalembert in one of the journeys when that illustrious Frenchman was collecting the materials for his "Monks of the West," Lord Dunraven was not insensible to the grandeur and importance of such ruins as those of the lonely monasteries which stud the western coasts of Ireland, and attract pilgrims to the wild rocks of the Skelligs. Beginning with the remains of the Pagan forts, heaps of stones hardly to be distinguished from those deposited by the slow action of Nature herself, he passes to the early Christian cells, and so to the primitive churches like St. Benen's Temple, which rises with its two gables formed of enormous blocks of stone on the precipitous edge of a limestone cliff in Aran Mór, at the foot of which rolls the Atlantic. One interesting practice of the early builders is related in the concluding essay on the history of Irish architecture. Over the doorway of many of the cells and oratories five or seven quartz stones, rounded and waterworn, whose whiteness is in marked contrast with the dark slate of the walls, are set in the form of a cross. These white stones must have been carried up laboriously one by one from the sea-shore far below by the builder of the cell, to set them in the wall, and so stamp his dwelling with the symbol of his faith. The relics visited and described by the author were not all overlooking the sea. The cathedral and tower of Clonmacnois were in the very centre of Ireland. The crumbling ruins of Leabamolaga, under a tall ash-tree, with a little mountain stream running along their south side, are in the midst of a delightful inland scene. The photographs show that not alone antiquity, or their beautiful situation, gives value to the remains, but that many of the buildings possess great architectural merits, and go some way towards proving the existence of an early period of civilization in Ireland, such as is attested by the evidence of manuscripts, and by the legendary history of the Isle of Saints. No doubt the extent of this civilization is often greatly exaggerated, but it should not on that account be altogether overlooked.

The process of decay, which does not spare the abbey and bell-towers on unfrequented Irish hills, is accelerated in London by the rude hand of the builder. Much is gained to health and convenience, but something is lost to the picturesque, by the removal of such landmarks of old London as the Oxford Arms Inn, which lately stood in Warwick Lane, with its quaint courtyard surrounded by dark wood galleries, and its "windows that excluded the light, and passages that led to nothing." When this ancient hostelry was about to be pulled down in 1875, a few artists and others interested in the antiquities of London determined to secure photographs of the ancient building, and so preserve the one thing about it which was really worth preservation. The proposal was made known

* *The Times*. A Review of "Notes on Irish Architecture," by the late Earl of Dunraven. Edited by Miss Stokes. Vol. I (1876), Vol. II (1877). London: George Bell and Sons. "Old London." Published by the Society for Photographing Relics of Old London. 1877.

in our columns, and received so much support that it was resolved to continue the work in similar cases, and a "Society for Photographing Relics of Old London" is now in existence. The photographs published by the Society comprise not only six views of the Oxford Arms Inn, but also houses in Wych Street and Drury Lane, on or near to the site condemned by the Metropolitan Board of Works, and St Bartholomew the Great, with Cloth Fair, a true Hogarthian background. Already in 1760 St. Bartholomew the Great, the chapel of the ancient priory in the close of which the great fair was held, was thought by antiquaries a precious relic. Maitland wrote, "On the south side of this church, the centre part of the beautiful cloister, consisting of eight arches, is still remaining, but it is reduced to the mean office of a stable." To judge from the appearance of the ancient houses depicted in the photograph, Cloth Fair has not long to be. Indeed, a building does not come properly within the original objects of the Society until it is threatened with removal.

Subscribers are asked to give intimation to Mr. A. Marks, Long Ditton, S.W., of the intended demolition of interesting buildings in their neighbourhood, and this must be done in good time. For example, it was intended to photograph, in 1876, some picturesque almshouses at Deptford, but when the artist went down to select the points of view for the photographer, the venerable relics had already been pulled down. We trust sincerely it is not meant that the gatehouse of Lincoln's Inn, in Chancery Lane, is also in danger, but that also, and some sets of brick-built chambers in Old Square, with curious chimneys, have been photographed for the Society. It may be hoped that, although the chambers fronting Chancery Lane will be pulled down in sections, the Benchers will preserve the gateway itself. The member of the Society who built this fine gatehouse at his private charge was a Knight of the Garter in Henry VIII.'s time, an honour which never now falls to lawyers. His arms (those of Sir Thomas Lovell) still adorn the gatehouse, on which are also placed the bearings of the Lacey family, Earls of Lincoln, with three wheat-sheaves for their constableness of Chester. Ben Jonson is said by Fuller to have laboured as a bricklayer on part of the buildings of the Inn; but the work he did in respect of Bartholomew Fair will not be so readily effaced from the earth. His play is freely quoted by Mr. Morley in his interesting book on the Fair. The photographs now published are clear, permanent, and taken from well-chosen points of view, and they show that even the blackness that comes of saturation for centuries with London smoke may have its æsthetic value.

THE EMULSION PROCESS.

THE *Scientific American*, in some remarks on recent progress in photography, gives the following details of the emulsion process:—

"The common method of photography, that universally practised in all galleries for portraiture, and for the best outdoor work, is known as the wet plate process. It consists in sensitizing the collodion plate by dipping in a liquid charged with nitrate of silver. The sensitization is effected in about three minutes' time: the plate is then withdrawn from the bath, quickly placed in the camera, and the picture taken and developed before the plate has time to dry. When all the chemicals are in good order, the bath pure, the exposure rightly timed, and the development skilfully done, the most beautiful results are produced. Indeed, there seems to be no room for improvement in picturesque details, as realized by the best wet plate operators.

"But the method is attended with many inconveniences and irksome details. The gallery photographer must keep in readiness a first-class bath, the purity of which is lessened by every plate that goes in; and the bath soon requires renovation. The plates cannot be prepared and sensitized so as to be ready for use in advance of the

opening of the day's business, but must be prepared and developed after the customer comes. Should the negative prove unsatisfactory, a new plate must be prepared and developed; and thus the bother of the plates involves the loss of so much time that the operator has little chance to consider the best positions for his subject, or to study the artistic accessories that go to make up a finished picture. For outdoor work, wherever the photographer goes, he must lug his bath along, even to the mountain top, and must there have a dark tent, and water for washing and developing; otherwise his efforts are fruitless. For several years past it has been the study of photographers to discover a reliable method of preparing highly sensitive plates without the use of the bath—a method by which the plates could be used when dry. Among the results of these efforts are a variety of dry plate processes, some of which, in the hands of skilled operators, yield excellent results. But nearly all of them have proved less sensitive or less excellent in their results than the wet process; and none have been able to compete with the latter for portraiture or gallery work.

"The French Photographic Society in 1876 offered a prize for the best dry process which should unite rapidity with all the other qualities that go to make a good negative. The competition was closed in December last, and the jury have recently awarded the prize to Mr. Alfred Chardon. The process appears to have advantage over some of its predecessors, but there are inconvenient details about the development, and some uncertainty in the summering and wintering of the emulsion; while the prepared plates require twice as much time for taking the picture as the wet plate. Moreover, the process is not suitable for the ordinary routine work of the gallery.

"The author of the new process which we have now to describe, and to which we would direct the attention of photographers as a complete and perfect substitute for the wet process, both for indoor, gallery, portrait, outdoor work, and all descriptions of photography, is Mr. Henry J. Newton, of this city, President of the Photographic Section of the American Institute.

"We have seen the process worked under the author's hands, and examined some of the results. We believe that practical photographers, when they come to examine the negatives and prints, will agree with us when we say that they are unsurpassed by anything as yet produced by the wet process. They will also agree with us that Mr. Newton's process is simpler, quicker, easier, less expensive, and more certain in the excellence of results than the old method. Moreover, for gallery and outdoor work it presents the striking advantage of enabling the photographer to prepare in advance a stock of sensitive plates, and of keeping them on hand ready for instant use when wanted.

"The Newton is an emulsion process. The silver is mixed with the collodion, which remains good for use at any time within a year or more. A glass plate is flowed with this collodion in the usual manner, the plate is then dipped in water; it is then ready for use either before or after drying. The picture being taken, it is developed by simply flowing the plate in the ordinary manner with a solution of carbonate of soda and pyrogalllic acid; then fixed with hypo or cyanide, as usual. This is all the manipulation required for the most beautiful, clean, and splendid negatives. As to sensitiveness, the Newton plates require, in the gallery, less than half the time necessary for wet plates. Portraits by the Newton plates are taken in from five to ten seconds; while the wet process, same light and lenses, requires from twenty to forty seconds. For outdoor work the Newton plates yield as good or better instantaneous pictures than wet plates.

"The exact formula for the emulsion has not yet been made known by Mr. Newton, but will in due time be freely given to the public. It is sufficient for the present to say that the emulsion is prepared with an excess of free nitrate of silver, which is allowed to remain for a certain number of hours, when chlorides are added."

COMMERCIAL DRY PLATES.

CAPTAIN TURTON returns to the subject of commercial dry plates, but states that he regards it as a scientific rather than a commercial question. We must confess that to us it appears to be essentially a commercial question, and that the grievance complained of must find its remedy in commercial issues. If a tradesman supply his customers with bad wares, they will soon cease to be his customers, and his occupation will be, like Othello's, "gone"! The old north country motto will naturally occur to the buyer, "If you deceive me once, shame to you; if you deceive me twice, more shame to me!" In short, no manufacturer can find his account in the sale of imperfect goods. Failure, utter and ignominious, must be the final issue of such a course. It may be admitted, however, that whilst this is essentially a commercial question, it is something more, as it involves scientific considerations. The photographic dry plate is unlike the mass of goods in trade which may be examined and judged of before they are purchased. They must be bought and used in faith: faith partly in the process by which they are alleged to be prepared, and partly in the trustworthiness of the manufacturer and vendor. The issues depending upon their quality are at times of great scientific importance, and are at all times sufficiently important. The chief drawback which has been at any time alleged to attach to the use of dry plates as compared with wet plates is the element of uncertainty. The wet worker exposes a plate, retires to his tent, and develops at once, and so ascertains whether he has or has not secured a satisfactory negative. If he have over-exposed or under-exposed, if the effect of light be unsatisfactory, if the point of view be ineffective, or if a score of minor points fail to please him in the negative, which were unnoticed on the ground glass, the exposure of another plate may remove every objection. The dry plate worker must take all these risks, and if his vigilance and experience enable him to avoid risk in such directions, it becomes doubly hard that all his effort and skill may be rendered nugatory by defective plates, whether the defect consist in stains, spots, or other of the imperfections which imperfectly prepared plates are heir to, and which are frequently due to manipulative carelessness in preparation. We regret to learn that these and other defects are not uncommon in commercial dry plates.

An enthusiastic and careful amateur, who recently called upon us, stated that, lured by the attractive accounts of the rapidity of certain plates, he had been induced to obtain some, but found it impossible to secure a negative free from defects. Captain Turton proposes a remedy in publicity. He argues, naturally enough, that it is somewhat hard for every photographer wishing to try commercial dry plates

to have to discover for himself which are bad and which are trustworthy. The experiment, he thinks, is too costly and heartbreaking. It is not simply the loss of the value of a packet of plates and all the chemicals used in connection with them, but the waste of time and the bitter disappointment which attend the enlightenment. He suggests that different photographic societies, who may be willing to aid in erecting beacons of this kind, should constitute experienced amateurs corresponding members of their bodies, and that these corresponding members should from time to time frankly and honestly state their experience of trade products in the use of which photographers are interested; and Captain Turton himself offers to undertake such position and duty. That such communications, honestly and ably written, would possess much interest there can be no doubt. But we must candidly admit that we should look for some thorns in the path of the executive of a society which should entertain such reports. Speaking the truth should be in such cases a desirable and safe thing; but there is, unfortunately, an undefined thing known as the law of libel in this country, of which journalists stand in wholesome awe, because of its uncertain and often capricious action: the winner in such a suit being often well-nigh ruined. A mild illustration of the risks of journalists came under our attention a day or two ago. Notice of action for libel having been served on a journalist of our acquaintance, on some frivolous ground, he felt it wise to compromise the matter by a payment of £10. Within a few days he received his lawyer's bill for the preliminary proceedings already taken in preparing for defence, amounting to £70. Thus he was mulcted of £80 for the insertion of what he believed to be an innocent and justifiable paragraph. One of the recognized conditions constituting a libel is the statement of anything which may injure a man in his business. If, then, a society read, or a journal publish, a paper announcing that the plates sent out by the Quinzie Dry Plate Company produce dirty and defective negatives, there is surely risk of the law of libel being put into operation, especially if the manager of such company possess something of that character which Byron claimed when he described himself as "being a Christian, and vindictive"! The journal publishing the report might, indeed, escape, as it has, we believe, been decided that a journal publishing a fair and honest report of proceedings which are libellous in themselves is exempt from action.

The cause of many of the defects complained of is doubtless due to manipulative carelessness and inexperience. There is a natural aim on the part of manufacturers to produce as cheaply as possible, and hence boys and girls are often employed in preparing plates: a bad economy, we submit, as, whilst the operations are quite within the ability of boys and girls, it is difficult to impress either with a sense of the great importance of extreme care. At any rate, we would strongly impress manufacturers of dry plates with the vital importance of securing the utmost avoidance of preventable defects, as a loss of faith in dry plates will effectually ruin their own business, and, by destroying all confidence in such plates, ruin this branch of industry altogether. Possibly if those manufacturers who feel perfect confidence in the excellence of their plates and freedom from defects would challenge the publication of reports of experience with their plates, they might do much to restore confidence, which is at present, there can be no doubt, much shaken.

THE COFFEE PROCESS.

OUR readers will remember details of the coffee process which appeared in our last volume, together with our remarks on the great excellence of the results forwarded to us by our esteemed correspondent, Mr. J. H. Whitehouse. We have recently been favoured with some further charming examples of the results of these coffee plates. Mr. Whitehouse has since the close of last year been in America,

and has only recently returned to Switzerland, and renewed his photographic experiments. We hope shortly to be able to publish his hints on neat manipulation to which we referred in the beginning of the year. Mr. Whitehouse prepares his plates and develops them in a bed-room, and might as easily do it in a lady's boudoir, without leaving stain or trace of his work behind him. He says:—

"I am once more settled in my old quarters here; have conveniently arranged my photographic *table* in my bedroom (which forms my sole laboratory), and feel myself both prepared and impatient to again take up the art of which I am so fond; and I hope to send you from time to time specimens of amateur work such as, I trust, may induce you and others to recognize, as fully as I do myself, that there is nothing superior, more simple, and reliable in the way of dry plates, *than those prepared by the coffee process*, to which I am so wedded. At present I am using some plates prepared in September last, and which have twice crossed the Atlantic; and certainly within that time their sensitiveness has not been impaired in the *slightest degree*, nor do I find it necessary, to-day, to give them any longer exposure than I should have done had they been freshly prepared.

"I avail of the opportunity offered by a friend going up to London to send you four prints and a transparency.

"No. 1 is a view in Prospect Park, near New York. Exposure twenty-five seconds. I found the light in America wonderfully quick, and from miscalculation in this respect spoilt two plates from over-exposure, giving them thirty-five to forty-five seconds, where twenty-five to thirty was ample.

"No. 2 is of the Suspension Bridge at Rouen. Exposure forty seconds, at six o'clock p.m.

No. 3. "Monument of the Cardinals" in the Cathedral at Rouen. Exposure one hour.

"No. 4. A view upon the Lake of Geneva, near to the little river Flon. Exposure thirty seconds; bright light, about eleven o'clock a.m.

"No. 5. A transparency of the last view. Exposure, six seconds in a subdued light.

"The clouds in Nos. 1, 2, 4, are printed in from a negative (also dry plate) exposed five seconds at 6-30 p.m.

All of these pictures were taken with the same lens, the only one which I possess—Dallmeyer's 6 by 5 Rapid Rectilinear, and the stop used was No. 3 for landscapes and clouds, and No. 2 for the interior.

"I have done more rapid work with similar plates; but certainly, with even the above results, *no one is justified* in pronouncing the coffee process a slow one, and in view of such evidence to the contrary I am surprised to see that Mr. G. W. Hewitt, in his paper read before the Photographic Society of Philadelphia, reprinted in your Journal of 1st inst., says: 'With me all dry plates are slow.'

"I have upon a previous occasion given you full particulars of the coffee process as I practise it, and so simple are all the manipulations, and so uniform the results, that no one need fear failure who has met with success by any other method.

"Should any of your readers feel tempted to give a trial to these plates, without desiring at first to prepare them for themselves, I would say that Mr. A. Bauernheintz, of this place (former associate of your old contributor, the late M. de Constance), a most intelligent practical photographer, and who makes use of the same formula as myself, will gladly execute any orders, even for two or three plates as samples; and I need scarcely assure you that to any one passing through this part of Switzerland, and bringing a line of introduction from yourself, I will take great pleasure in showing my 'boudoir laboratory' (in which I take great pride), and all of the little that I know of the 'coffee process.'

All the prints forwarded are excellent, and indistinguishable from the results of the wet plate process. Those of

our readers who may chance in their holiday rambles to be in the neighbourhood of the Lake of Geneva will do well to avail themselves of the privilege of calling upon Mr. Whitehouse, at Ouchy, where he will be easily found.

DESPAQUIS' PHOTOGRAVURE PROCESS.

[THIS method, to which our Paris Correspondent recently called attention in these columns, we now publish in *extenso* from the *Moniteur de la Photographie*.—ED. P. N.]

My process is based upon the observation that an engraved plate should possess a grain in the hollows, while the surface should be of a polished character. It matters little whether the bottom of the deeper hollows, which are to furnish the deep blacks of the image, have a larger grain than the shallower ones, which yield the half tones; the tool of the engraver makes the same kind of markings wherever it penetrates; it is the breadth and depth of the hollows themselves which produce either deep blacks or half-tones, as the case may be. All parts of the plate not touched by the grain should remain perfectly polished, so as not to retain the ink spread over it, and thus soil the whites of the picture.

There is nothing new in these observations, nor do I claim them as my own; neither do I lay claim to the employment of grain in the gelatine; but what I do call my own, and which belongs to me morally, since I have given my process to the public, is the means of making practical use of the observation above made, and this I do by having recourse to a *second very thin film of gelatine which is absolutely free from grain, and which is laid upon the surface of the first and thicker film that contains the grain*. This second film, very thin and without grain, is the main point of the process. It is by its means that I obtain all the delicacy of the half-tones, which, without it, would be heavy and charged with black ink. In fact, the fine half-tones being represented in the gelatine image by a film of gelatine of extreme thinness, it is impossible for the same to cover up and annihilate the grain, no matter how fine it may be; and when the film is dry the grain will be found still in relief, and capable of producing, by the aid of a counter-mould, an engraved plate having in the fine half-tones hollows many times deeper, and consequently capable of producing small half-tones with the same distinctness as large ones. This is but the theory of the process, and I now proceed to practical details:—

Preparation of Paper.

Ordinary water...	1,000 grammes
Gelatine...	200 "
Indian ink for giving a slight tint	20 "
Pumice stone finely ground and sifted through fine linen	4 "

It is requisite that care be exercised in adding the pumice, for if too much is put in, the grain produced is too close, and the impression will not develop well in warm water; those who employ the process will, however, soon get to know the proper amount that should be used. In any case, however, too little rather than too much should be employed.

I use pumice stone in preference to other powders, because it has a tooth which catches the surface, and also because it is light, and consequently remains well in suspension in the gelatine solution, and does not settle at the bottom, and thus prevent the preparation of the paper uniformly.

It is for the same reason that I employ a gelatine solution of twenty per cent. strength, because it is thick, and the sooner it sets after application to the paper the better, since the gelatine has not then time to settle at the bottom of the film. The gelatine solution for the same reason must not be too warm at the time it is poured, and should only be heated sufficiently to spread in a uniform manner, its spreading being facilitated by inclining the surface.

The gelatine solution should first of all be filtered before the powder is added through a bit of fine linen, and indeed I generally filter twice. After the first operation I maintain my solution warm in a decanter placed in a water-bath. At the moment of application upon the plate or the paper, I shake up the liquid in order to get the powder in suspension, then quickly I cover the mouth of the decanter with a loose piece of linen, and pour out my gelatine, thus filtering it a second time. This second filtration is, however, only for the purpose of arresting the passage of air-bubbles, which form at once on shaking up the solution. To work in this way it is necessary that the gelatine should be pretty warm.

If the precautions mentioned are taken, and there is no fear of the powder falling in a mass to the bottom of the film, the solution may be poured upon a plate lightly coated with ox-gall, which will yield a paper with a very fine polish; the grain arrested by the plate will be found enveloped by gelatine, and not in relief, when dry. But if you do not wish to take so much care in the matter, you may wax a plate, and, having placed upon it a sheet of moistened paper, and driven off all air-bubbles, you can pour the gelatine solution upon this, and let dry. What is wanted is a paper with a thick film of gelatine upon it, containing a very fine powder or grain, which must be equally disseminated throughout the gelatinous mass.

This first film with grain is to form the interior of the hollows of the engraved plate, and when dry it may be preserved for use till wanted.

When required, it is sensitized by being immersed for one or two seconds in the undermentioned solution, according as to whether the latter is still warm or not. If the liquid is too warm, and the prepared paper is allowed to remain therein too long, the grain will dissolve out, and the gelatine will run. The liquid is made up of:—

Water	500 grammes
Gelatine	10 to 15 „
Dichromate of ammonia	15 „

The gelatine paper is immersed in this liquid, prepared side uppermost, and a glass rod is passed rapidly over the surface to remove all air-bubbles. Then it is withdrawn by taking hold of two corners and slipped upon a glass-plate (prepared with ox-gall), the paper side undermost. When dry the sheet separates without difficulty.

I have already explained the utility and indispensability of this second thin film of gelatine, which is altogether free from grain, and it is unnecessary, therefore, for me to make any further remark, except to add that this second film dispenses with the burnishing of the whites, and permits one to obtain the most delicate tones in a photograph. The slight wave-like formation upon the surface of the gelatine which always takes place on drying, and the hardening with alcohol of the gelatine prior to taking the counter-mould in lead, often necessitates subsequent burnishing, however, in those parts where there is no grain from the pumice.

As soon as the paper has received this second film of gelatine, and has been rendered sensitive, it is dried in the dark, and is then cut to a size rather larger than the cliché; the gelatine side is put against the negative, as in carbon printing, and the paper exposed to light for a third longer, or even half as long again if deep hollows are required, than would be necessary to secure a carbon impression.

After exposure, the operator proceeds as in carbon printing, but instead of allowing the impression to adhere to albumenized paper or glass, the former is applied to a sheet of polished steel or copper. When adhering to this surface the image is put under a press and allowed to dry, when it is developed in the ordinary way with warm water. It is necessary, however, to use a little more care in development than if the transport were paper or glass, and especially when dry, for too much heat will speedily bring about a stripping of the film from its support.

I employ either steel or copper for the support, so as to

be able to make the counter-mould without difficulty under a hydraulic press. For this purpose a sheet of lead is employed, and if a hydraulic press is not to be had, then a rolling press can be made use of. The image is covered with a very stout sheet of lead doubled, and the latter is then covered with a zinc plate. This is passed several times through the rolling press until the lead has penetrated into the very finest details of the image.

From the gelatine counter-mould another is secured by the electro type process, which serves as the printing plate to receive the ink, and which may be retouched, if such a process is necessary.

THE PARIS EXHIBITION FOR 1878.

So many rumours have circulated about the postponement of the Paris Exhibition, that our readers will be glad to hear something definite in regard to it. So far, no steps have been taken to stop the preliminary measures which are in progress, and the workmen engaged upon the *Champ de Mars* are still vigorously labouring upon the vast building which is to enclose the international collection. Moreover, we hear that experiments are being undertaken with a view to ascertain the best means of illuminating the building with electricity. The electric candle will, doubtless, be the means employed in the end, and this will be supplied with electric fluid from huge Gramme machines to be worked by steam power. If the Exhibition is only instrumental in introducing into ordinary use electric illumination, and proving beyond doubt that the employment of this valuable mode of lighting is adapted to every-day purposes, this alone will be one great step of progress for which the civilized world will be thankful.

So far as the photographic department of the Exhibition is concerned, matters are apparently in a very forward state. Already the names of all intending exhibitors have been received, and the latter have been requested to vote for a hanging committee. Two delegates are to be chosen, it appears, and the administration committee have nominated four gentlemen, namely, MM. Andra et Chardon, amateurs, and M. Joliot, whose firm of Levitsky is well known, and M. Levy, the successor of Ferrier et Soulier, whose transparent stereoscopic slides are known all the world over.

We have no means of knowing as yet the number of native and foreign photographers who have applied for space, but there is every prospect, notwithstanding the war, that the Paris International Exhibition for 1878 will be no less a success than the preceding gatherings in that capital.

FRENCH CORRESPONDENCE.

PROCEEDINGS OF THE FRENCH PHOTOGRAPHIC SOCIETY—GOUGENHEIM'S RAPID COLLODION—HUSNIK'S PHOTO-LITHOGRAPHIC PAPER FOR TRANSPARENTS—BARDY'S EXPERIMENTS WITH COLOURS—A SUITABLE PIGMENT FOR DARK ROOM WINDOWS—PREPARATION OF EMULSIONS IN LARGE QUANTITIES.

THE monthly meeting of the French Photographic Society was held on the 6th July, when many interesting communications were made. M. Gougenheim, who is well known for the beautiful photographic enamels he has been so successful in producing, forwarded to the Society for trial among its members, several bottles of collodion of a very rapid description. The formula for making this collodion M. Gougenheim forwarded also, and this was as follows:—

Ether	535	cub. cents.
Alcohol at 40°	465	„
Pyroxyline	10	grammes
Double iodide of potassium		
and cadmium	5	„
Iodide of ammonium	4	„
Iodide of cadmium	24	„
Bromide	3	„

The silver bath employed is up male of seven per cent. strength, and the development of the image is undertaken by means of an iron solution male up in the following manner:—

Ordinary filtered water	... 1 000 cub. cents.
Ammoniacal iron	... 50 grammes
Sulphate of copper	... 20 "
Acetic acid...	... 35 "
Alcohol at 36°	... 20 "

If the image should not appear to be sufficiently vigorous, it is intensified with the undermentioned liquid:—

Distilled water	... 500 cub. cents.
Pyrogallie acid	... 5 grammes
Acetic acid	... 20 "
Alcohol at 36°	... 80 "

The silver solution which is added to the above when necessary to intensify is a three per cent. solution. M. Truchelet, who has tried this collodion, declares that by employing the iron bath indicated by M. Gougenheim very great rapidity indeed may be secured.

M. Schœffner the same evening exhibited to the members some specimens of photo-lithographic paper prepared by M. Husnik for transferring to stone or metal images in line or in grain. This is the way in which M. Schœffner told us the paper is employed. One hundred grammes of bichromate of potash are dissolved in 1,500 cub. cents. of distilled water, and ammonia is added until the liquid becomes yellow and begins to have an acid reaction, when 400 cubic centimetres of alcohol are added. This preparation will keep in good condition by adding to it from time to time an additional quantity of ammonia and alcohol. When you desire to sensitize your paper, you carefully pour, as if decanting, the liquid into a flat dish, and steep the sheet of paper, its prepared side uppermost, in the solution. It is then withdrawn forthwith and dried. When wet, the surface should not be permitted to touch anything. In inking the sheet after printing, ordinary lithographic ink is employed, of which five parts are taken with a little wax, the whole being dissolved in essence of turpentine, until it is of the consistence of honey. The printed sheet is placed upon a piece of cardboard, and upon it is dropped a little of the ink in question. The latter is spread over the surface by means of a bit of very soft linen, and the excess is subsequently removed by employing a fresh bit of linen and passing it over the print. The latter is then of a uniform grey tone, but nevertheless contains quite enough ink for the purposes of transfer. Five minutes after this operation the sheet is placed in water, and you proceed with the development ten or twenty minutes afterwards. The development of the image is effected with the aid of a fine sponge. As soon as the picture appears in all its details, it is put between two sheets of blotting paper, and sponged softly, being slightly pressed meanwhile. After the transfer has been thus treated, it may be applied to the surface of stone or metal. Every time the image is subjected to pressure, which is increased in the press several times, a sheet of dry paper is put upon the image to absorb the moisture. It is then moistened again, passed through the press several times, and then well moistened once more; finally, the paper backing of the image is carefully removed. The whole of the picture will then be found resting upon the stone or metal, and it is treated in the same way precisely as an ordinary transfer. When zinc is employed, in order to prevent the sheet from attaching itself too firmly to the metal surface the impression is plunged after development in a bath composed of one thousand grammes of water and fifty grammes of alum.

A skilful chemist, one M. Bardy, has communicated a very interesting note upon the subject of a substitute for glass in laboratories or dark rooms. M. Bardy has discovered by experience that the yellow glass usually employed for such purposes admits, under certain conditions, enough

light to produce a positive upon glass by contact printing. He therefore set himself to study the different colouring matters which may be employed, and which are for the most part the products of coal tar. He has examined them all by means of the spectroscope, and he has found the best of all to be *crisoidine*. This substance, which is of an orange-yellow, is soluble in alcohol and in water. It may therefore be employed both in the form of a varnish or paste for paper and glass indifferently; by mixing with gelatine a tinted pellicle may also be produced. It is a product, however, which is to be obtained at the present moment only of one manufacturer, and this manufacturer is in England. M. Bardy has convinced himself by repeated experiment that this colour does not permit any chemical rays to pass, while at the same time it admits sufficient illumination for a dark room or laboratory.

M. Bardy, who has adopted the process of M. Chardon, and who has sometimes occasion to prepare three litres of emulsion at one time, naturally feels the labour of producing this large quantity very considerable, and the fatigue consequent upon such a task has led him to make some modification in the process. He now finds he is able to allow the preparation of the emulsion to proceed mechanically: he simply places the vessel containing the liquid to be shaken upon a sort of balance, or scales; this balance works simply by a stream of water, which automatically turns the balance. Every time the balance goes to one side or the other, the emulsion is, of course, shaken up.

The interesting meeting of which I have spoken concluded by the presentation on the part of various gentlemen of collections of carbon prints, and of pictures produced by Scamoni's greasy-ink process. A demonstration also took place showing the nature of the development which is necessary in the case of dry emulsion plates prepared in accordance with M. Chardon's process.

ERNEST LACAN.

INVESTIGATIONS ON IRON DEVELOPERS.

BY ROTTIER AND WALDACK* (*Chemisches Centralblatt*).

THESE investigations on iron developers were carried out with the view of ascertaining which are the substances most suitable for the composition of iron developers, and what are the conditions under which they give the most favourable results. All the experiments were made on the wet collodion process, and in each experiment two negatives were prepared under the same conditions, and treated with different developers. In order to obtain two equally latent images, a stereoscopic apparatus with a glass plate of nineteen by eleven cm. was employed, the objects taken being the same in each case. After exposure to light in the camera, a strip of glass was placed in the middle of the layer, and first one half of the plate developed, then the other half. In another experiment the glass was scratched along the middle by a diamond, and after preparation and exposure broken in half. The following observations were made:—

1. *Influence of a Concentrated Iron Solution.*—It was found that while a dilute solution developed slowly a thin, transparent violet image, concentrated solutions gave at once dark, dense pictures. A weak solution penetrates through the layer of the collodion, producing a precipitate of silver throughout the whole of its thickness, while a concentrated solution yields an image only on the surface of the layer. The stronger the solutions, the stronger are the negatives. The manner in which the development takes place, apart from the concentration of the solution, influences the consistency of the precipitate to some extent, different results being obtained accordingly as the developer is left at rest on the glass, or moved up and down it.

2. *Influence of Acids.*—In the above-mentioned experiments solutions of ferrous sulphate without addition of

* *Journal of Chemical Society.*

acid were used. It is known that the development of images is retarded by acids, different acids showing different results. Organic acids in general produce black precipitates, excepting acetic acid, which gives a very clean negative, and is of great value to the photographer. Glacial acetic acid, commercial acetic acid, and wood vinegar, all give the same results. Sulphurous acid yields a worthless picture, whilst the action of sulphuric acid is as advantageous as that of acetic acid. The greater the quantity of acid used with the developers, the less quickly is the photograph developed, and the weaker is the negative obtained.

3. *Influence of Various Iron Salts.*—With salts other than ferrous sulphate different results are obtained. With regard to the fineness and strength of the images obtained, the following order is given:—1. Ferrous nitrate develops weak images. 2. Ferrous sulphate. No difference is perceived in the results of this preparation, either obtained from the metal or from its ores by the action of sulphuric acid. 3. A mixture of equivalents of ferrous sulphate and cupric sulphate acts in the same manner as ferrous sulphate alone. 4. Ammonio-ferrous sulphate. This salt has a more advantageous action than ferrous sulphate, less time being required for exposure. 5. Ferrous acetate is to be preferred to the former, as it requires still less time of exposure to the light.

4. *Observations Regarding the Use of Ferrous Acetate.*—By adding a small quantity of ferrous acetate to the ordinary iron developer its sensitiveness is increased very considerably, intense negatives of harmonious tone being obtained. With too large a quantity of the acetate, however, a confused photograph is obtained. Indeed, the extraordinary sensitiveness of this salt, which enables it to produce negatives of great intensity, renders its action, on the other hand, too rapid for the development of powerful pictures.

Correspondence.

O. G. REJLANDER.

DEAR SIR,—Your readers will be glad to hear that steps are being taken to furnish the hitherto unmarked resting-place of the late O. G. Rejlander, in Kensal Green, with a suitable grave-stone. One of Rejlander's old friends, and a sculptor of some note in Sheffield, has generously promised to erect a suitable head-stone, bearing upon its face a bronze medallion of the well-known artist. The medallion is about ten inches in diameter, and the stone bearing it, while simple in design, is of a handsome and solid character.

Of the competence of the gentleman to execute his self-imposed task I need say little. Being a labour of love, Mr. Theophilus Smith may well be relied upon to execute a faithful likeness of the master of photographic art, whose friends and disciples were legion; and when I mention that Mr. Smith boasts of possessing the largest and most complete collection of Rejlander's works, there is little need to tell of the admiration which the sculptor feels for his dead friend. The portrait, I am told, is finished for casting, and the stone has simply to be lettered with a simple inscription to be ready also. Mr. Theophilus Smith's standing as an artist is too well known to require any introduction to photographers; and if he is as successful in the present instance as he has been in the case of two excellent busts of Mr. Roebuck, M.P., and Professor Sorby, F.R.S., recently executed by him, we shall all owe him a deep debt of gratitude. To those as yet unacquainted with his ability, I would mention that there are to be seen just now at the Royal Academy two very able productions from his hands.

Mr. Smith suggests that it would be desirable to make the monument more complete, and to enclose the grave with a coping-stone or rail. To do this satisfactorily, as also to cover certain incidental expenses, I desire to collect a sum of from ten to twenty pounds, and I now invite any

of your readers to aid in subscribing this amount. I shall be happy to give an account of all monies in these columns, if you, sir, will permit me; and I trust to be able to forward you, in a few weeks' time, another note stating that the whole work has been well and satisfactorily completed.—Faithfully yours,

H. BADEN PRITCHARD,
Late Treasurer to the Rejlander Fund, and Hon. Secretary to the
Photographic Society of Great Britain.
Royal Arsenal, Woolwich, July 9th.

NOTES ON GOLD.

SIR,—The following notes on gold may probably prove useful to many of your readers.

NOTE 1.—Gold is the most valuable—and probably the longest known—of all metals. From the remotest period it has been esteemed for its beauty and permanence. At the present day it contributes, as we all know, to the enjoyment of life. This may be going beyond the limits, and photographers will say we only wished to know about the chloride of gold; but all in good time. But the impatient must remember that without the genuine article "gold" there would be no chloride of gold. A few incidents I also noted about the genuine article, which may be of interest to some: They are these. In California a mass of gold weighing twenty-eight pounds was found; whilst in our Colonies one weighing one hundred and six pounds was dug out, containing upwards of ninety-one per cent. of pure gold and nearly eight and a half per cent. of silver, being as pure as the English sovereign, or, in trade language, twenty-two carats fine.

Now for the impatient comes the well-known chloride. Trichloride (Au Cl_3) is prepared as follows: Gold, one part, is dissolved by aid of heat in nitro-hydrochloric acid eight parts, and evaporated down to dryness, and allowed to crystallize.

PROP.—Orange red crystalline needles, deliquescent, soluble in water, in ether, and alcohol, and forming a deep yellow solution; at the heat of 500° Fahr. it suffers decomposition, chlorine being given off and pure gold left behind; it is reduced by oxalic, sulphurous, formic, and phosphoric acids.

NOTE 2.—As well as most metals to metallic gold, it combines with several metallic chlorides, forming a series of double salts.

USES.—Its most important is in photography, where it is used as a re-agent, quantities being made for toning photographic prints. To some extent it is used in electro-gilding, with excess of bicarbonate of potash.—I remain, yours truly,

C. R. P. VERNON.

Grafton Underwood, Kettering

P.S.—I have an excellent toning formula; if any of your readers desire it, they can have it on application to me. As I shall be going a short tour, they must direct to C. R. P. Vernon, Alveston House, Alveston, Gloucestershire.

[Our correspondent will do well to send us the formula for publication, which proceeding will save him trouble, and extend the benefit he contemplates.—ED.]

COMMERCIAL DRY PLATES AND THEIR VALUE

SIR,—I see that you have called attention to the letter I wrote you under the above heading in your paper of June 22nd, and am glad that you have done so, thinking, as I have long done, that "commercial dry plates" should be looked on by all photographers (and by a scientific journal devoted to photography especially) in other than a mere commercial point of view. I may say that I used the word "commercial" in my letter more with the view of calling attention to it than any other reason, knowing well that some of those who "manufacture" the dry plates care much more about their own pockets than the advancement of photography, and that my letter would certainly be read if these gentlemen thought their monetary interests would be affected for good or evil in any way, while it would be

neglected if the mere scientific aspect of the value of dry plates were brought before them. In taking the "commercial" view I quite agree with your article, for of course a public journal cannot express its opinions, good or bad, of articles advertised for sale in its pages; but I never expected the PHOTOGRAPHIC NEWS to do more now than it has done hitherto by giving publicity to comments which bear directly on the advancement of the photographic art in a public sense, nor do I ask more now.

The value and the merits and demerits of various dry plate processes have occupied the columns of the photographic journals of various times very fully, and perhaps no person has taken more advantage of this fact than Colonel Stuart Wortley, especially in his criticisms on the processes and inventions of others.

That the value of dry plate processes to science and art is increasing, and must increase, is evident from your own recent pages. In your three last numbers you allude to the value of dry plates in micro-photography, in relation to what the French Government is doing in its museums and galleries, where dry plate processes alone are admitted—this must give an important impetus to dry plate work in France. In your French Correspondence of June 22nd M. Ernest Lacan alludes to the exclusion of photographers from the public museums and galleries of France, owing to the mess made and injury done in working the ordinary wet process, and the damage done by them. Dry plate processes must now be used, and our so-called "professional" photographers must now learn how to handle dry plates, either by the alkaline or acid mode of development.

With regard to the value of criticism of dry plates, the fact is that emulsion processes are so (comparatively speaking) in their infancy, that those who prepare the plates should court inquiry as to their various qualities, as to rapidity and general excellence of final results; and the various photographic societies are well capable of examining specimens brought before them under the microscope. I should, therefore, suggest that some of the societies would affiliate gentlemen like myself, who reside away from any photographic centre, as *corresponding members*. We might send specimens and papers to the societies, and the general interests of photography would be furthered. No one knows better than dry plate manufacturers that at least nine out of ten of those who use commercial dry plates know little or nothing of photography, either wet or dry, and that, therefore, the vendors of the plates can send any rubbish they have in the way of plates, knowing the workers do not know a good plate from a bad one, or whether the faults lay in the plates or in the development of them.

For myself I have, during the past five or six years, exposed and developed some hundreds of dry plates (chiefly commercial) by the Liverpool, uranium gelatine, and Russell, modes of preparation, and my boxes are full of negatives and transparencies on these plates, and those prepared by myself from emulsions. I claim, therefore, full acquaintance with the various modes of working these very different plates, and shall be happy to show them to any gentleman interested in dry plate work who may come to Bedford. You have spoken well in the NEWS of some of the nearly instantaneous pictures of animals exhibited by me from these plates in the Photographic Exhibition. In your YEAR-BOOK for 1876 there is an article of mine, "Commercial Dry Plates and their Value," and directly that appeared I received a letter from one of the gentlemen whose plates I alluded to, acknowledging fully the justice of my remarks, but stating that many of those who might read my paper would not, probably, comprehend their full meaning. I shall further state that some four years since I wrote a letter to your journal describing and criticising some plates sent me by Colonel Wortley. The gallant gentleman did not quite relish my description of his plates, and wrote me he would reply in the NEWS. I waited some weeks in vain, and on asking Colonel Wortley why he did not reply to my letter, he wrote me that if he did so he should have

to allude to the number of bad plates sent out by "another company," which would not have been prudent. I have the letters from both of these gentlemen, and they both fully bear out my testimony as to the badness of plates at times sent out by those who manufacture them.

As regards my own experience in photographic work in general, as "A Manufacturer" seems to hint that inexperience may be the cause of failure, I may state that I have worked at photography now for nine years, both at wet and dry work; that I have spent some hundreds of pounds on photography; and that rarely a day has passed during these nine years in which I have not done some photographic work in a well-appointed studio, and have had the advantage of the advice and companionship of such men as Messrs. R. M. Gordon, Blanchard, Rejlander, and others.

For the past eight or nine years I have read your valuable weekly journal with attention and interest. In an excellent article entitled "The Camera as a Plaything, and the Camera as a Scientific Instrument," you describe well the people who look on that instrument from each point of view. For myself, I can only say that photography has been to me a labour truly, but a labour of love, in which time and money have been ungrudgingly spent, and I cannot be content to look upon an art I love so much, and respect so greatly, merely from a commercial point of view. Some of the manufacturers of dry plates I know to be gentlemen who take a pride in perfecting their several processes, but there are others who care little for the goodness of their dry plates, provided they can get rid of them for a high price.

Dry plates may be looked on in photography as cartridges for breech-loaders are by the sportsman: when good they are of the highest value; when bad they are worse than useless.

FRANCIS W. TUTOR.

Proceedings of Societies.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

ON Thursday, July 5th, the members of the Board of Management held their monthly meeting at 17½, Fleet Street, and transacted the following business.

The minutes of the previous meeting having been read and confirmed, Mr. Ehlers was elected an ordinary member of the Association.

The half-yearly balance sheet was then placed before the meeting. After being carefully examined, it was adopted unanimously.

Various estimates for printing the new edition of rules were then considered; the selection of one having been made, the Secretary was instructed to expedite the issue.

A motion was brought forward "That any member of the Board of Management not having attended six monthly meetings of the said Board in the course of the year, dating from the time of election, shall not be eligible for re-election." After some discussion on the subject, it was proposed by Mr. Lavender, seconded by Mr. Attwood, and carried.

Grants for various purposes having been issued, the meeting adjourned till August 2nd.

WEST RIDING OF YORKSHIRE PHOTOGRAPHIC SOCIETY.

THE members and friends of the above Society held their second monthly excursion on the 6th inst. to Milner Field, the seat of Titus Salt, Esq. Most of the party arrived by the 1.50 p.m. train at Saltair Station, whence they proceeded to Saltair Park, where it was proposed to wait till the remainder of the party arrived. A few pretty views were taken of Saltair from here. The park appeared to please the members very much, but the other members appearing at this time, it was decided to lose no time in making for Milner Field, where, through the kindness of Mr. Titus Salt, the party were allowed to look through the grounds and conservatory, and through his splendid greenhouses, where he grows a large quantity of vines. Afterwards they proceeded to Shipley Glen, a romantic and very popular little place.

After enjoying themselves on the Glen for an hour or so they began to think that tea would be very acceptable, so set off for Shipley, where a substantial knife and fork tea was provided.

After tea there were playing and singing and a little dancing. The party were compelled to break up rather early, on account of catching the train. All agreed that they had had a very pleasant holiday. It is proposed to go to Temple Newsum on the 1st of next month.

Talk in the Studio.

COPYING AT NIGHT.—Mr. T. C. Harris writes in the *Practical Photographer*:—"I have been in the habit of making copies of photographs or other pictures at night, when busily engaged during the day. This is how I do it: Place the camera and picture to be copied in the proper position, and when ready to expose, hold a kerosene lamp near the picture, in such a way that the light will fall on the picture in the same direction that it fell on the subject when the original picture was taken. Now place behind the lamp a silvered glass reflector, so as to concentrate the light on the card, and while exposing, keep the reflector in motion, so that the picture will be equally lighted all over. Expose three or four times longer than in daylight, and use the developer double strength, or vary the time to suit each case. By this means I have made as good copies at night as in daylight. The lamp should have an Argand burner, and the reflector should be a glass one, such as is used on bracket lamps."

TO SENSITIZE TISSUE IN HOT WEATHER.—I place the tray in a tray of cold well water, just pumped, and find it reduces the temperature to about 50°. I also have a large plate glass lying in water of the same temperature. I then immerse the tissue in the sensitizer, and when it curls the opposite way I place it face down on the glass, from which the water has been thoroughly removed with a squeegee used only for that purpose. Cover the tissue with rubber cloth and squeegee thoroughly; then apply a blotter to the back to remove all drops of sensitizer, and lift immediately from glass and hang in the dark. All the above I do in a well-lighted room where I can see what I am about. I can then hang it up and fear nothing even when the mercury shows a temperature of 95° anywhere in my rooms. There is no need of cooling the glass after the first time, but sensitize all you wish at that time; it won't stick.—Dr. WITT C. ROOZE.

A WORD OF CAUTION TO CARBON PRINTERS.—A great many photographers may not be aware of the very poisonous properties of the salts of bichromate of potassium or ammonium, now used so much in carbon printing, photo-engraving, &c. We would, therefore, like to call their attention to an article published in a late number of Dr. Hornig's "Photographic Correspondence," in which he says that these salts are to be dreaded and handled as carefully as arsenic or bichloride of mercury. The effect of this poison, when taken internally, was an inflammation of the mucous membrane of the mouth and throat, with cramps in the stomach. The hands and feet would turn cold, become paralyzed, and finally death would ensue. In case of poisoning, send immediately for a doctor; in the meantime, give to the patient milk and the whites of some eggs, and try to keep the extremities warm by rubbing them with alcohol and a little aqua-ammonia. It seems that some persons are more prone to be affected by this poison than others. Be careful to wash your hands well after having had them in a solution of the bichromates, and avoid contact altogether when the skin on your hands or fingers is any way abraded or sore. The pustules caused by this poison are very difficult to heal, and our carbon readers, we hope, will take warning by what we have just said.—*Practical Photographer*.

To Correspondents.

G. F. R.—The chief defect in your card is simply the result of using an unsuitable lens. The image is only illuminated in the middle, and the definition is only approximately perfect in the middle of the plate. You have, apparently, a very bad quarter-plate lens, which is quite unsuitable for standing figures in card portraiture. You must get a lens suitable for the work. This one may be improved by using a small stop, but the exposure will be much longer. What you require is a lens made for producing card portraits.

HOPKINS ARTIST.—In order to print an enlarged image direct on albumenized paper, you would require a solar camera with very large and powerful condenser; and the exposure with continuous sunlight would be from one to three hours. There is no method of enlarging so effective and so easy as that of making an enlarged negative and printing from it. You may produce an enlargement on paper by a few minutes' exposure in a solar camera if you employ iodized paper and develop the image, but the trouble is very little less than that of producing an enlarged negative, and the result not nearly so good. Your former letter, to which you refer as not receiving answer, never reached us.

C. NORMAN.—We have not heard whether space has yet been awarded to photographers in the Paris Exhibition of 1878, but we think not. See a short leader on the subject.

SINCERITY.—We think your love for photography, and your honest desire to improve, are fair bases for success, and we should advise you to persevere. Do not be discouraged because you were brought up to another business. Almost all the men whose names are distinguished in photography were brought up to other trades, and they adopted photography and succeeded in it from love of the art. You have, of course, much to learn. Study art whenever you have opportunity. Read all the works on elementary art you can meet with, and try to understand them and to digest and assimilate the information they contain. Study good pictures whenever you can, and try to understand in what their excellence consists. Keep on practising photography whenever you have opportunity. Do not be in a hurry to give up your own business until a favourable opportunity occurs. And then, when that happens, you will be able to accept it with increased fitness from continued culture. Your work is very promising.

DILKAMA.—The chief of the markings in your negative are, we think, from the use of turbid collodion, the residue at the bottom of a bottle having been apparently disturbed and mixed up with the bulk of the collodion. The comet-like markings with a nucleus or head, and long, curved tail, suggest a defect common in simply iodized collodion; to cure which the addition of about one grain per ounce of bromide of cadmium might be used. There are a few pinholes proper, which may arise from the bath; if they are caused by sulphate of silver, the addition of nitrate of baryta, say three grains to each ounce of nitrate solution, may prove a cure. The addition of distilled water to an over-iodized bath will, of course, make it turbid, and, unless the iodide of silver thus precipitated be carefully removed by filtration, the pinholes will be worse than ever. We see no reason to suppose that the defect was in any way due to the distilled water.

EDWIN L. PENNY.—We do not know of any special portable camera used by the war artists in the East. There are many which may be used, which you will see announced in our advertising columns; but we are not aware that any special form is used in preference to others.

D. K. M.—You will find many articles on the coffee process in our last volume, and you will find it succinctly described in our last YEAR-BOOK.

H. J. JEN. wishes to know what process goes on when a plate coated with collodion is immersed in the nitrate of silver bath. He "presumes" that the object is to allow the film to absorb some of the silver solution. The process is not quite so simple as our correspondent "presumes" it to be. The collodion with which the plate is coated contains iodide and bromide, probably of potassium. Iodine and bromine have great affinity for silver, and silver has an affinity for them; hence, when they are placed in a solution containing a salt of silver, a combination takes place. A process called double decomposition enables this combination to be made; the silver leaves the nitric acid to which it was joined in nitrate of silver, and joining the iodide and bromide forms iodide and bromide of silver, and the nitric acid set at liberty joins the potassium which has been left by the iodide and bromide, and forms nitrate of potash, some of which remains in the film, and the remainder passes into the bath. The iodide and bromide of silver formed constitute the salts which are sensitive to light. In the emulsion process the sensitive salts of silver are held in suspension in the collodion.

HOPKINS.—The tone is excellent, and the prints very good. No. 3 is too deeply printed, however.

G. G.—Your discoloured whites in the copy of the engraving arise from the fact that your negative is not sufficiently intense; and the light prints through the opaque parts of your negative before the blacks are sufficiently deeply printed.

AMATEUR MECHANIC.—A good dipper may be made in various ways. Silver wire answers well. A piece of plane tree or poplar cut to the right shape, and well saturated with paraffin or wax, answers. We generally take a strip of stout plate glass, and cement on it a shoulder, on which to rest the plate, with marine glue. It is wise to place the shoulder an inch or two from the bottom of the strip, so as to keep the plate away from the sediment of the bath.

J. GREER.—Thanks. In our next, several Correspondents in our next.

The Photographic News, July 20, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

THE JURORS AT THE NEXT PHOTOGRAPHIC EXHIBITION—THE LATE O. G. REJLANDER—HOT AND COLD DARK ROOMS—PHOTOGRAPHY BY MEANS OF LIGHTNING.

The Jurors at the Next Photographic Exhibition.—We are glad to hear that the Council of the Photographic Society have induced two Royal Academicians to act as jurors at the next Exhibition of the Society in October. One of them, moreover, occupies the distinguished post of President of the Society of Painters in Water-colours, so that every one must perforce feel satisfied with a verdict recorded by a body of which two artists of such high reputation form part. Mr. E. W. Cooke, R.A., and Sir John Gilbert, R.A., are the names which will be found included in the list of jurors, the other gentlemen being the President of the Society (James Glaisher, F.R.S.), one Vice-president (Captain Abney, R.E., F.R.S.), one other member of the Council (Mr. T. S. Davis), and two members of the Society (Mr. Faulkner and Mr. Piercy). Such a list of names ought to give satisfaction. Mr. Cooke, R.A., who paints with almost photographic exactness, is particularly competent as an artist to judge photographers, and the jury includes men also who are so thoroughly conversant with the science and technics of photography as to know what belongs to it, and what does not. Altogether, there is every reason to hope for a good exhibition this year, and we sincerely wish that it will be of such a nature that only good things need be hung, and that the walls will not be filled with common-place pictures as well as deserving works, for the reason that something must be done to cover them.

The late O. G. Rejlander.—It is gratifying to learn that the grave of O. G. Rejlander, at Kensal Green, is no longer to remain without a monument. We are aware that the placing of a gravestone over the resting-place of this talented artist has for some time past been contemplated, and several gentlemen we know expressed their willingness at the time of Mr. Rejlander's death to join hands with this object in view. Fortunately the initiative has now been taken in a very energetic manner, and before the summer is gone a suitable stone with a medallion of the deceased will have been placed in Kensal Green. Mr. Theophilus Smith, to whom photographers owe the first step in the matter, is a sculptor whose works are known at the Royal Academy, as well as at Sheffield, where he has executed several busts of local celebrities. Mr. T. Smith had already finished his clay model of Rejlander, and as he has done his work with the skill of an artist and the love of a friend, we may safely rely upon the result being a satisfactory one. Mr. Smith not only gives his labour, and makes a present of the bronze casting, but provides a well-wrought stone to receive the medallion, which will be consigned to Kensal Green from Sheffield ready lettered and in a fit condition to be at once set up. To render the work more complete, however, it is suggested that a coping-stone or neat railing should enclose the grave, and this, together with the fixing of the headstone, will entail some small expense, towards which many will no doubt be pleased to contribute. It would be pleasurable to see a large number of photographers upon the subscription list, each subscribing a small donation, rather than that the amount should come out of the pockets of a few of the late Mr. Rejlander's friends and acquaintances. There are many who have benefited by his precepts and his works, and these would do well to aid in setting up a monument to the clever artist who has so recently left us, and whose name must long remain a household word among those who strive to infuse art into their photographic work.

Hot and Cold Dark Rooms.—Summer is *par excellence* the season for dry plates and for emulsion work. The difficulties attendant upon the nitrate bath, the keeping moist of the collodion film, and maintaining solutions cool, are of such a nature as to make one renounce wet plate photography in bright sunny weather. At the same time there are magnificent wet plate pictures to be secured in the intervals of cloud and sunshine which we have lately experienced, if only the laboratory and solutions can be kept not only cool, but cold. On a recent occasion we had an opportunity of seeing some negatives taken which had been prepared and developed in a cellar, the exposure-taking place in a well-lit landscape. The clichés were of a degree of brightness and clearness seldom seen. Not a stain or pinhole was visible, while the gradations were delicate and fine throughout. The whole batch of negatives were good throughout, and although the bath had been giving trouble previously, a sojourn of twenty-four hours underground caused it to do its work faultlessly. And this result set us thinking whether in large establishments it would not pay to employ underground laboratories and dark rooms in summer time, the plates being sent up to the studio by a carefully constructed lift as required. Such an arrangement would be not only profitable, but pleasurable. To endeavour to secure good portraits in some of our studios in the dog days is heart-breaking work, and in dark rooms that adjoin the glass room, and have the sun pouring down upon them all day long, we wonder that negatives can be taken at all, at any rate free from stains and drying-marks. At one studio, in Paris, which we visited in summer, we once observed a negro-operator, working away in a smoking dark room in his shirt and trowsers, and we consoled ourselves with the idea that he was probably better fitted to bear the stiflingly hot temperature than an European. Since then the reminiscence has often come to our mind when cooped up in a dark cabin in hot weather. How to keep cool is, indeed, the main problem for the photographer in hot weather, and he is often sadly taxed to bring down the temperature. His dark room is, however, as a general rule, right under the roof, and from the fact that the slightest crevice will let in a vivid daylight, it is necessary that every crack and fissure should be stopped up. In these roof dark rooms ice melts like sugar in a cup of tea, and I have seen photographers in their despair swaddle the collodion bottle in flannel, and drench the latter with costly alcohol or ether to keep down the temperature by rapid evaporation. Could not our studios manage to have a studio below stairs, and if a lift is impracticable, then, perhaps, a portable cold cupboard, capable of carrying half a dozen dark slides to and fro, might serve the purpose. There is nothing like this summer weather to secure clear and delicate pictures, but then plates, bath, and developers must be cool. A sheet of glass, when perfectly cold and dipped into cold solutions, will remain a long time before it grows warm again; but if a plate is warm to begin with, and the collodion and bath are not cold, the film dries very rapidly. There is no such photographic weather as that which we are at present enjoying, but it needs to be taken an advantage of, and made proper use of.

Photographing by Means of Lightning.—Mr. Jarman's experiments with lightning as a means of illumination are exceedingly interesting, and should not be passed over without notice. He managed to take a view of Queen Street, Ramsgate, being lighted, as it was, by twenty flashes one after another. No doubt the illuminative power of a bright flash is very intense, and if he could have made choice it is possible Mr. Jarman might have secured a picture with less than half this number of flashes. A single flash, he tells us, was sufficient to print a negative by contact upon another film of collodion, a fact we can readily believe, since a quickly revolving wheel has been ere now depicted in the camera by the aid of a single electric flash.

LIGHTS AND SHADOWS IN A PICTURE:

THEIR USE AND VALUE, WITH OTHER SUGGESTIONS, FOR ART-STUDENTS.

BY MARCUS A. ROOT.

ALTHOUGH persons ignorant of artistic effect may find fault with the most effectively disposed lights and shadows, I would earnestly counsel every photographer to study and give to his productions the highest possible artistic value. This he should do not alone for his own reputation, but for the honour of his art and its professors. If insensible to these motives, he may well doubt his possession of the qualities indispensable to his profession. At all events, a skilful, delicate use of lights and shadows is essential to the production of those heads truthfully modelled and well "rounded up," which can win for their author the proud name of artist.

In nature the intensest lights and darkest shadows are always sparingly employed, and this invariably in points, and never in masses. If the light be in a large mass, it is subdued; and the shadow, if broad, is feeble. The interval between such contrasted light and shadow is occupied by middle tints and pale greys. Into this scene nature introduces here and there a spot of high light, and here and there one of intense gloom; the effect of which is to vivify the whole. Her invariable rule, then, would seem to be to furnish the same amount of deepest shadow as of intensest light, and neither more nor less—points of each answering to those of the other, and both showing vividly out from the rest of the landscape. Such is nature's method of managing light and shadow; and herein the artist has a model which he should strive, to the extent of his ability, to copy.

Masses of diffused, soft light, balanced by masses of expanded mild shadow; the space betwixt the two filled by carefully graduated middle tints; while here and there a keen, bright spot of light is set off by equivalent spots of deep shadow. Here is the programme which the wielders of the pencil and the camera should alike endeavour to conform to, and the nearer they approach it the more do they exhibit the genius and executive skill of the artist.

These principles, we were pleased to find, had been seemingly vigorously observed and carried out, too, by several of the leading landscape and portrait artists, both foreign and American, whose grand, and we may say marvellous, productions attracted so much attention while on exhibition in our International Centennial Exposition, 1876.

It is impossible, on paper, to tell the Photo-Artist—the new beginner—how he can make his own simple instrument execute a work so complex and delicate. But if he have the eye of genius, there will need but industry and perseverance in observing and experimenting to discover the *modus operandi*; besides that, he may be essentially aided by an accomplished artist—if out-door or landscape art is his study—to point out the most favourable spot from which to take his view, select and fix the hour of the day for artistic effect of light and shadow, and direct his attention to the needful accessories, a rock, tree, stump, clump of brushes, weeds, &c., or the want of these, in the foreground, and to the proper handling of the camera, both in the field and in the studio, before the eyes of the novice in art. An art-student of nature, with the above aid, will readily perceive that what we call "relief" (i.e., the apparent standing out of the object from its ground) is effected by the contrasting of light and shadow. So, would you produce breadth and splendour of effect, join together masses of light objects and corresponding masses of dark objects. Again, to get harmony and softness, sink some objects partially or wholly in shadow, and let their outlines be insensibly lost in the ground. Finally, to create vivacity and spirit, make, in some parts of the picture, abrupt breaks and sharp transitions.

In portraiture, let your shadows fall at the proper angle

on the face, be decided, pure, transparent, and effective. The lights and shadows on the face or other parts of the picture must be managed with the greatest care, in order to produce rotundity, relief, harmony, and life-like effect. When the broad or short side of the face is mostly in shadow, the shaded cheek should, if possible, be tipped with light, to give it a pleasing fullness and natural-seeming roundness. The model (sitter) should be so placed under the light in the studio as to project short shadows, the light being sufficiently subdued to preserve the half-tints, while the time of exposure is long enough simply to develop or secure the image completely, without meanwhile "overdoing" (i.e., solarizing) or flattening the picture. So, too, all strong cross lights and reflections should be carefully avoided, and special pains taken to impart the utmost rotundity, boldness, and force, to all portions of the figure. As a faithful likeness is the chief desideratum in portraiture, the mere head and bust are preferable to a larger proportion of the figure. In some it should, if practicable, when more than the head is taken, indicate the breadth across the shoulders with the relative size of the body, when the portrait is set in an oval frame or case. Artists generally prefer painting short shadows on the narrow side of the face, in a two thirds or a three-fourths view. Occasionally we encounter an admirer of Rembrandt's or Vandyke's manner, wherein the shadows are so broad and strong as to shade deeply nearly half the face. Unfortunately, however, for the photo-artist, many, if not most, of his patrons, like England's "Queen Bess," prefer "pictures without any shadow at all!" If you would give to a spare, thin face, with high cheek-bones and deep wrinkles, a fuller, younger, and more attractive appearance, you must reverse the general rule. Thus, to impart to the face and head the utmost possible boldness, energy, rotundity, &c., place the subject (sitter) so that in a two-thirds or three-fourths view of the face the face may, from the point of sight, or eye, or the part focussed upon, be almost totally in shadow or so that the shadow may fall from the cheekbone backwards towards the ear. By this means, with a clear, distinct shadow on the side of the nose and face, and a soft, mellow light along the cheek, a picture is obtained upon a flat surface which, wondrously "relieved" from its background, exhibits all the roundness and solidity of nature. The artist who is fully alive to all the requirements of his profession will find that nearly every successive subject needs a different arrangement of light and shadow, with a different location in the studio view of the face, &c. Accordingly, his genius (for nothing else can) will suggest such a change in the position of the camera, in the position of the background, and in all other conditions, as is required for the object aimed at. And, as the reputation alike of himself and his establishment must rest on the artistic merits of his productions, so every successive picture is a proof, patent to all capable judges, either for or against his pretension to the title of artist.—*St. Louis Practical Photographer.*

HOW TO CLEAN DAGUERREOTYPES.

[A CORRESPONDENT of the *St. Louis Practical Photographer* sends to that journal a thoroughly practical article on cleaning Daguerreotypes, a process but little understood by modern photographers. We can endorse the instructions, having many times proceeded similarly with success. We recommend using distilled water solely.—Ed]

To clean Daguerreotypes perfectly; so many ways have been published, so many Daguerreotypes have been spoiled beyond redemption, by so many ways being tried, by so many who did not understand cleaning them. If the photographer, or even the old Daguerreotypist, follows the following instructions closely he never will injure one, and clean it perfectly, so that it will be as brilliant as the day it was taken, if it has not been defaced by rubbing the surface of it. First, all films, spots, and chemical action can be

removed by the following method, and by no other that I have seen published or heard of. Now bear in mind, the secret is hot water; where it should be used I will state. Second, when a party brings a Daguerreotype to you to copy, or restore, as they call it, if there are no defects on it, carefully take it apart, brush the surface with a fine camel's-hair brush crossways the position of the picture, never up and down; then copy it. Third, if there is a film of some or all colours of the rainbow, spots or stains on it, have ready some hot water, cyanide, a pair of pliers, spirit-lamp, and some distilled water. Next, proceed as follows: First, see that the water is filtered and clean, cyanide also; brush as directed above; then take hold of your plate with the pliers, pour on the hot water first, leaving it on the plate for about a minute, more or less; that softens the film of imperfections that is on the Daguerreotype plate or picture. The hot water is the whole secret of cleaning, with the other things mentioned. Cold water may do, and may not, as I have often found out, but hot certainly will. Next, pour the hot water off, and pour on the cyanide solution, and it will immediately eat off all imperfections; then wash the picture, and it will become as brilliant as when it was first taken. As soon as the imperfections disappear, which will be in a few seconds, pour off the cyanide solution, and rinse the plate well with distilled water; lime-water would spoil the picture, rain or soft water might do; then, with your spirit-lamp in one hand and your pliers holding the plate in the other hand, commence heating the plate from the upper corners, and blow gently with your breath on the plate till it is perfectly dry; do not stop blowing till it is so, for it is liable to leave a stain where you would stop off blowing and commence again. After this, seal up the picture well with sticking paper, leaving no breaks in it to let in air on to the picture, for that is what causes the defects on the plate, the action of the atmosphere on the gold surface that is over every good Daguerreotype picture. Now, you will have as perfect a picture as the day it was taken. For such jobs we get from one to five dollars, according to the condition and size of the picture. I was once offered fifty dollars to restore a fine and valuable Daguerreotype that seemed as if it was entirely obliterated; I took my five dollars, and was satisfied. Although we have published how to clean Daguerreotypes before, letters come in asking us to give them our process, if it is not secret.

THE FERROTYPE.*

It is astonishing what a multiplicity of names the positive picture goes by. Some will call into your gallery and call for some gems; others want ferrotypes, bon-tons; another party wants anotypes; but the majority want tintypes, and open wide their eyes and mouth with astonishment when you tell them they are one and the same picture. Call them by what name you may, they are very pretty pictures when well taken, especially when you put them in cases and seal them up. Photographers who do not take plate pictures, as we shall call them, have no idea of the extent to which that branch of the business is carried, especially in the country. We have no doubt but what there are two artists in this line of the business to one in photography. As a general rule they are cheap pictures, and the business is easily acquired, which no doubt is the cause of so many practising it. Of late years it has become quite fashionable to go tenting it through the country. It is a very pleasant way to spend the summer, and there are not millions in it, but there is money in it when you understand the business and start out right.

We give below a very good formula for plate pictures, one that can be relied upon, all other things being favourable; but the great trouble in all processes and formulas is not having all things right—one in harmony and keeping with the other. We will cite one instance

* St. Louis Practical Photographer.

here. Your collodion is right; your bath is right; your time and developer are right; you work all right for a few days, then all goes wrong. Your opponent does the same, but he is still all right. You wonder what is the matter. To test the thing, you coat your plate, and dip it in his bath, you using all your own chemicals otherwise, and it comes out all right. You wonder. Your friend tries the same dodge in your bath, and all works wrong. Now the cause is, you have a bath that holds, we will say, a pint, and his holds a quart. Yours gets out of order first. It wants more solution—in fact, the bath is entirely too small to work to advantage. No gallery should trust to one bath. Always have two for plate pictures and two for negatives, and half of your troubles will be over. A bath should never hold less than a quart, up to two gallons. The inventor of small baths should be voted a nuisance, who is dangerous to the photographic fraternity. In preparing your bath for plate pictures, if you expect to get fine effects with that style of picture, it can be done by being particular in all things, especially your bath. Take any quantity of distilled or soft water and dissolve it into thirty-five grains of silver to the ounce, and if you are careless or too lazy to make some iodide of silver to sensitize it with, why coat the largest plate you can get in your bath with collodion, and dip it in the bath and let it remain till morning; then take it out, coat a plate, and you will find it will work all right; but after you mix your silver and water, test for acid, and if it is not acid, put in about twenty drops to the quart; test with litmus paper, and if it is pretty red it will work well. It should be much more acid than the negative bath to make brilliant results. If you wish to make your own collodion, here is a very good and reliable formula.

Collodion.

Iodide of ammonium	...	5	grains to the ounce
Bromide of potassium	...	2½	grains to the ounce
Ether and alcohol	...		equal parts.
Cotton	...	5	grains to the ounce.
Bath, 35 grains strong to the ounce.			

Developer.

Water	...	16	ounces
Proto-sulphate of iron	...	1	ounce
Acetic No. 8	...	1	"
Alcohol	...	1½	"

Fix in strong solution of cyanide of potassium. In mixing your collodion, dissolve your bromide of potassium in water enough to dissolve it.

Mix your collodion in the following order:—Alcohol and cotton, shake well up; ether next, shake till dissolved; then your iodide; then pour off a couple of ounces of your collodion on to your bromide solution, and it will take it up better; then pour it back into the balance of your collodion; let it settle after well shaking, and it is ready for use the next day, when it grows better and better the longer it is made; its keeping quality for about three months is first rate, then it will work slower; but if you have any business at all, you can work up the quantity you make in that time. The best plan is to make up small quantities, say about sixteen ounces at a time.

THE USE OF THE DIAPHRAGM.*

WHETHER it was necessary to go to the Greek for a word to be used in a business like ours, which does not require a classical education, is a question we will not at present discuss; suffice it to say the word diaphragm is from the Greek, and means a partition or division. In photographic instruments it is hardly appropriate; to be literally correct, it should have been "a cutter off," "a hinderer," for which a shorter word could have been found in the same language.†

Some time ago an old photographer, in our hearing, boasted that he could put a patch as large as a dime right

† Nothing is better than the common term "stop"—*En. Photo. News.*

in the centre of his lens, and make a good negative—better than without it—and he claimed something extraordinary for his lens on this account. At first this appeared like idle boasting, but it was literally true. We were so puzzled that our coming grey hairs got to rubbing against each other, and, by-and-bye, a solution of the problem was ground out. For the benefit of our young readers, we give it as briefly as possible.

A photographic camera tube for portraiture is composed of four lenses, mounted in pairs—a pair in front hermetically sealed together, and a pair behind fitted to each other, but separated by a ring differing in thickness according to the size of the lens and the curvature adopted by the maker. Between these pairs of lenses the diaphragm is placed.

Few photographers study the philosophy of either the process they practise or the instruments they use. Chromatic aberration and spherical aberration are terms they know in the books and journals, but beyond this their knowledge does not extend; and if, by chance, one posted a little better happens to mention such a term, he is at once set down as "hifalutin" and anxious to show off in the style of the coloured missionary who but yesterday was a wood-sawyer.

Now, to render the subject intelligible, we will illustrate by an exaggeration. We will suppose a photographic lens to be four inches diameter, and ten inches focus, with a spherical aberration of one inch. Now, as the aberration increases towards the edge of the lens, it is evident that if we cut half an inch all around, leaving an aperture of three inches, we have got rid of more than one-fourth of the aberration; but for the sake of simplifying we will suppose it to be one-fourth, and divide the lens into four divisions, which we will number 1, 2, 3, 4. Number 1 is the central inch, a circle of one inch in diameter. Number 2 is a ring half an inch wide and two in diameter. Number 3 is a ring half an inch wide and three inches in diameter. Number 4 the outer half inch of the lens. The aberration we will also divide into fourths, and number 1, 2, 3, 4. Number 1 will represent that portion belonging to number 1 division of the lens, and situated from ten and a quarter to ten and a half inches from the lens. Number 2 will be immediately in front of Number 1, by which we mean nearer the lens, and will extend from ten to ten and a quarter inches. Number 3, following Number 2, will occupy from nine and three-fourths to ten inches; while Number 4, being nearest the lens, will extend from nine and a half to nine and three-fourths. The open lens being ten inches focus, it will thus appear that the longest division, or Number 1, including only the central rays which pass nearly straight through, extends half an inch beyond the common focus; while Number 4, which includes only the outer rim of the lens, falls short by half an inch, as before stated. This is not absolutely correct, and is used merely as an illustration to explain what would be very difficult to explain accurately even by the aid of diagrams, and is utterly impossible without them. Of course, every photographer knows that each atom of surface on his lens transmits a picture of whatever is before it, and the aggregation of these atomic pictures forms the picture seen on the focussing glass of his camera. He also knows that the aberration referred to, and which requires the diaphragm to correct it, is caused by the light rays striking the curved surface of his lens at different angles, increasing toward the edge, and that the greater the angle the greater the refraction. In the case we have supposed, for illustration, the difference is set down at one inch. Now, let us suppose our old photo. to have used the four-inch lens we are speaking of, and to have covered up the central inch; he then had divisions 2, 3, and 4, with a spherical aberration reduced from one to three-fourths of an inch. The lens would work slower but sharper, and he would get a better picture than without the patch; increase the size to two inches, and the aberration, being reduced to half an inch, there would be a further gain in sharpness, but a loss of light, and, of course, the lens would work

more.

A writer in the *Mosaic* touched on this question, and asserted that a disc perforated with holes answered almost the same purpose as a diaphragm, and he was puzzled thereby, and well he might be; a disc perforated as his was, would certainly reduce the speed, but it would not in any way affect the spherical aberration, inasmuch as the centre of the lens and parts of the outer division being exposed, the aberration would be the same; but, as parts of the lens were covered up, a proportionate loss of light and speed would be the result, without in any way affecting the aberration. Now, as it is to get rid of the blurring and lack of sharpness that the open lens necessarily gives that a diaphragm is used, it is evident that by reducing the aperture of the diaphragm the aberration on the basis of our supposed case is proportionately reduced; but in actual practice it will be found that the proportion of aberration cut off is much greater at the edge of the lens than nearer the centre; consequently a diaphragm covering divisions 4 and 3 will cut off much more than half the spherical aberration, and, as the use of very small diaphragms in portraiture is attained with such a loss of light as to render them inexpedient, they are very seldom used. It might be asked, if it is true that a patch in the centre will answer the purpose of a diaphragm, why not use it? We reply, it does not answer the same purpose, as the rays passing through the centre of the lens are less refracted, and consequently yield a better picture; but as some old photos. like occasionally to puzzle their younger brethren, we have tried to show why a patch on the middle of the lens does not prevent its making a picture, as some parties think it would. We have heard a person assert that a patch on the centre of the lens would give a picture with a hole in the middle of it, and argue long and earnestly to sustain his assertion.

The position of the diaphragm is also a thing to be considered; the front lens catches rays reflected from the object, and transmits them in converging lines to the rear lens, which, catching them converging, increases the convergence by a second refraction; the placing of the diaphragm between the front and rear lenses of the portrait combination cuts off the outer rays of the front lens, and shuts off the outer part of the rear lens. A disc in front of the front lens the same size as the diaphragm placed between the lenses reduces the speed of the instrument much more, while the diaphragm between gives the better picture; the reason of this we may take up at a future time—our present object is merely to show why a diaphragm is needed; why a patch on the front lens does not prevent it making a picture; and why a perforated disc does not either prevent the lens from making a picture, nor act the part of a diaphragm.

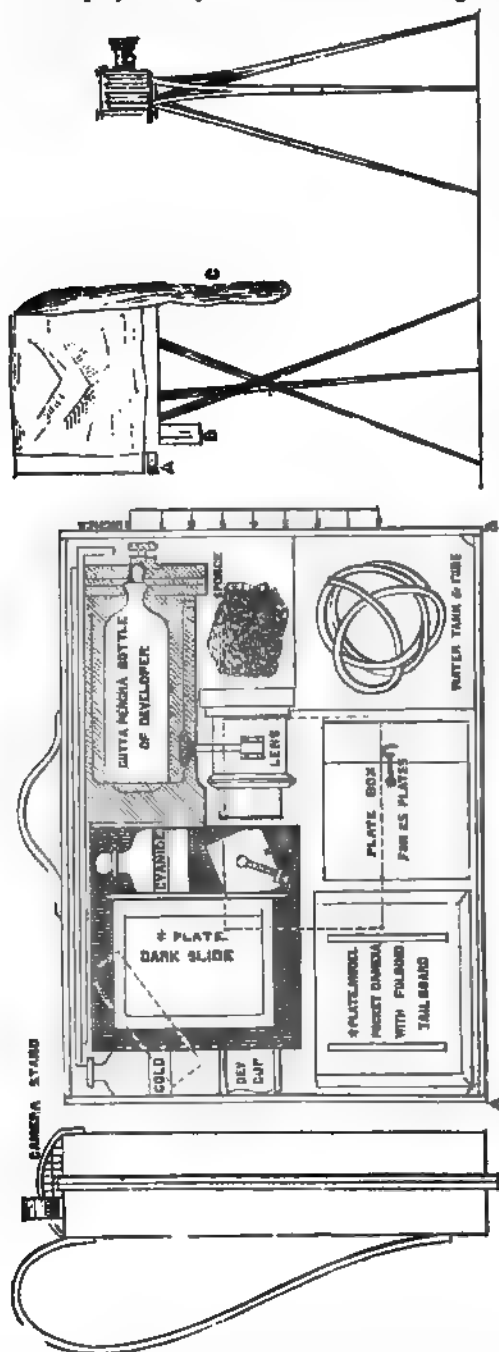

PORTABLE PHOTOGRAPHIC APPARATUS.

BY A. TROTTER.*

Now that the photographic season is approaching, I think a description of the tent I took to Switzerland with me last year may be of some use to intending photographers. I decided to use the ordinary wet plate process. After inspecting most of the tents made by the best makers, as none suited me, I contrived a combination of their best points. I had made a box consisting of two trays hinged to one another at one side—it measures about three-and-a-half by eighteen by thirteen inches when closed. I have only a sketch of it by me, and have calculated it from it. This sketch almost explains itself as to the packing. The dark side, cyanide bottle, and some screws for fixing the camera and tent are put into a glass dish, which was the heaviest part of the concern. This is shaded in the sketch, as also is the ebonite bath. This latter was dropped into a hole represented by the dotted lines in the corner, and hung by the ledge round the top. This hole is closed by a shutter when travelling. The other dotted lines show the position of a window of yellow glass at the bottom of the tent. A pocket handkerchief or a piece of paper being put on the ground below the negative may be watched

* *English Mechanic.*

during development while in a horizontal position. The glass window can be lifted up when the plate is being washed. This also is projected by a shutter when travelling.

At the top of the box in the sketch are three brass tubes, two of which have angles soldered to them. When fitted together they form three sides of an oblong, nearly the same size as the box. The two free ends are placed in sockets at the corners, A and B. The box is hinged on the side to which the leather handle is fixed, and when in use as a tent the two trays of which it is composed are fixed open at right angles, a cover of black and yellow cotton is thrown over the rods and all, and secured round ledges fixed to the edges of the tray by an elastic band. This is not a very safe method, but I never had an accident from its becoming unfastened.

The tent was fixed upon a folding tripod, something like a large campstool, while the camera stood on the stand supplied with it, the legs of which had been divided half way down, and fitted with ferrules. These legs were strapped on to the box outside when travelling. The tent stand is supposed to be used as an alpenstock, but is not strong enough. A better one might be contrived. The tent stands about four feet from the ground.

The water-tank is fastened to the upper tray, and when in use is in the upper right-hand far corner of the tent. In packing up, the lower tray is arranged as in the sketch, and the cover is wrapped up and laid over all. I found it difficult to carry water in the tank, and it only holds enough for two plates, so I had to refill it every time, which was inconvenient, especially at the top of a glacier.

The developer (ammonio-sulphate) was not injured by the gutta-percha bottle. I emptied what remained each day into a stock bottle, and refilled it just before starting. I did the same to the bath in which the dipper is always kept. The whole affair weighed about eleven pounds, not including the glass dish. This was used for washing into and developing over, but the window could have ledges fastened to it to serve as a dish. I had thought of this when the tent was being made, but did not know the dish would be so heavy, or I should have had it made so.

The other sketches represent a side view of the tent when closed, showing the shoulder-straps for carrying on the back, and the tent open for use—A being the handle, B the bath, C the loose hood going over the operator's head and arms, and coming down to his waist. I shall be glad to make anything clearer, and shall value suggestions, especially from Mr. Lancaster, who made the tent, and knows more about the model pocket camera than most people.

COLLODIO-CHLORIDE.

BY MERCER.

PREPARE two collodions as follows:—

Collodion No. 1.

Alcohol	2 ounces
Ether	3 "

Negative gun-cotton (Anthony's) 00 grains.

Put the cotton in a bottle, allow it to soak a few minutes, then add the alcohol, and shake till the cotton has all dissolved. Take one hundred and twenty grains of nitrate of silver, powder it very finely; put this in a small bottle with three ounces of alcohol; set this bottle in a dish of cold water, and heat up until the alcohol boils, and the silver is all dissolved. As soon as this is effected, pour the silver solution, while still hot, in the collodion given above, stirring all the time to secure a perfect solution.

Collodion No. 2.

Alcohol	4 ounces
Ether	4 "
Chloride of strontium	32 grains
Citric acid	24 "
Negative gun-cotton	00 "

Reduce the strontium and citric acid to a fine powder (together), and dissolve in the alcohol; add the ether and the gun-cotton afterward. If adding the ether produces a precipitate, filter it out (through paper) before adding the cotton.

These two collodions are to be kept separate until wanted for use; then mix in equal parts, adding No. 2 to No. 1.

White Varnish.

Gum sandarac (picked)	1 ounce
Alcohol	4 ounces
Chloroform	1 ounce
Balsam fir....	1 teaspoonful.

Mix, dissolve, and filter.

Use, slightly warming the plate; keep tightly corked when not in use; add, occasionally, chloroform, to make up for evaporation.—Practical Photographer.

CLOUDS IN LANDSCAPES.

ONE of the most effective and pleasing revolutions which have characterized landscape photography of late years is the general introduction of clouds into the prints. The most perfect photographic landscape with a staring, hard, blank mass of white for the sky, killing all the lights in the foreground, and utterly destroying atmospheric effect, was an unsatisfactory affair. It was as untrue to nature as it is offensive in art. It is in the sky, as Ruskin observes, that nature has done more for pleasing man with beauty than in any other of her works. "There is not a moment of any day of our lives," he adds, "when nature is not producing in the sky scene after scene, picture after picture, glory after glory." Surely, it is one of the most important functions of photography—the art of truth, and which boasts itself in rendering recondite truths scarcely visible to the eye—to attempt to catch these fleeting beauties of nature, and give the crowning beauty to scenes from nature, by adding clouds to every presentment of a landscape. Happily, the importance of this kind of work has been recognized of late years, and a landscape with a blank white sky is now as rare as one with natural clouds was a dozen years ago.

We have recently received from Mr. A. Ford Smith, of Llandudno, some charming illustrations of the value of clouds in giving pictorial value to landscapes. They are all fine, but some, in which ranges of mountain form the extreme distance, are especially charming; the delicate floating clouds seem to take up the suggestion of space and distance indicated by the faint tender outlines of the hills, and carry the eye away into infinite space. This fitting selection of a sky, the lights and shadows of which shall harmonize with the lights and shadows in the landscape, and of a character which shall give value to its salient features, is true art. We have also received from Mr. Smith some examples of the cloud negatives he publishes for the use of the profession. These are on paper made transparent by waxing, and possess many advantages over glass negatives for this purpose. They may, for instance, be used on either side, a convenience in suiting the form of the clouds to the composition of the landscape which only those who have worked in this direction can fully appreciate. The slight trace of texture in paper is a positive advantage in securing an effect of atmosphere. Mr. Smith's residence on a seacoast on the west gives him unusual facilities for obtaining grand skies and effective clouds, as the examples we have received furnish evidence. The variety of effect in each negative gives them especial value, as by moving the negative a little up or down, or

laterally, a totally different sky may be given to different landscapes, from the same negative. Paper also possesses advantages in being easy to handle, or to cut, and presenting no risk of breakages.

As these negatives are issued at moderate prices, as may be seen in the announcement of the publishers, Messrs. Marion, on another page, they come readily within the reach of everybody, and they will, we doubt not, materially contribute to improve and elevate the character of many landscape photographs.

A TOUR THROUGH BRAZIL.

HERR HEILER, a member of the Berlin Society for the Advancement of Photography, who has just returned from a tour in Brazil, gave an interesting account of his work and adventures at a recent meeting of his brethren in the Prussian capital. A large collection of stereoscopic pictures which he had taken excited considerable interest from the circumstance that they represented for the most part the primeval forests of Parana, and included much wild and impressive scenery. Some wonderful formations of rock to be met with in that part of the world were depicted, as also many groups of local Indian tribes, whose portraits proved of particular interest, although the lady members of the races appear to have no claim to be considered beautiful.

Notwithstanding the many difficulties which Herr Heiler experienced in his travels, the pictures he brings home are very clear and clean, and despite climatic vagaries are possessed of excellent detail and delicacy. Accompanying the photographer on his cross journey through the country were two friends, an architect and an engineer. Eleven mules served for the transport of the luggage, and two blacks acted as attendants. The apparatus had need to be very solid and well packed, for not only were the attendants exceedingly careless, but the path through forest and jungle, which had frequently to be cut with the axe, necessarily presented repeated difficulties, and many and hard were the knocks to which the packages were subjected. Moreover, mules have the disagreeable quality of throwing off their load whenever they can, and unfortunately there is little opportunity on the way to repair damages.

The subject of provisions also caused the party some anxiety, and everything pretty well had to be taken along with them, since supplies were rarely to be obtained on the road. The best food to transport was dried meat (since it was portable and light, and could be preserved good for a long time), and a small kind of black bean, together with coffee and flour. Water seldom failed, but it was little good calculating upon game; there is plenty in the dense woods and thickets, but it was not easily come-at-able.

The luggage of the party was packed in good stout boxes, not too large, of which each mule carried two, one on each side. The harnessing and packing require, however, particular care, for the animals are easily wounded or injured, and are thereby incapacitated from acting as pack animals. Hamlets or plantations are rarely met with. The traveller is kindly treated by the inhabitants, but must pay dearly for all necessaries. Coffee, for instance, cost in Brazil, where coffee is grown, three times as much as in Europe. In regard to the Indians, they are a little difficult to deal with, since the traveller is unacquainted with their language, customs, and habits. Above everything it is necessary to be provided with a sufficiency of presents for them, in the shape of glass beads, coloured cloths, and, indeed, any glittering or coloured articles, which need not be useful so long as they are pretty to look at. At the same time showy articles should be avoided in one's attire, such as shining buttons and buckles, as these provoke the envy of the Indians. With the aid of such things to barter and exchange, one can get on very well with the Aborigines.

The fear of the mules and dogs for wild animals is very remarkable; they easily detect an old resting-place, even if it is fifty paces distant. Of poisonous snakes Herr Heiler found no lack, but the bite of these reptiles may, it seems, be easily cured by dropping ammonia into the wound, and drinking some of the same in a dilute form.

The improvising of a resting place for the night, and the preparation of the evening meal, were the most tiresome tasks, because they often came at the end of a fatiguing day. The labour of journeying was very great, and as there is an absence of bridges, where unfordable rivers were met with a raft had to be constructed. The mules were unloaded, the goods and *personnel* placed upon the self-constructed float, and in this way the party was ferried across, the animals being left to follow by swimming.

The cost of the expedition, which lasted from the 17th May to 9th December, is calculated by Herr Heiler at 2,000 thalers (£300), a high price, but accounted for by the costly character of provisions and necessaries. The result is a series of three hundred negatives of stereoscopic character, taken on nine by eleven-inch plates. The collodion Herr Heiler took with him from Germany was found to be unserviceable on his arrival at Brazil, having been destroyed by the heat, and he was compelled to set to work and make some fresh material for himself. In fact, all Herr Heiler's work was done with freshly prepared collodion, made just before use.

PIGMENT PRINTING IN SUMMER.

Dr. VOGEL, who has now for some time past occupied himself not only with the theory but the practice of carbon printing, publishes a few notes in the *Photographische Mittheilungen* as to pigment printing in hot weather. As everybody knows, who has had the least experience in working with bichromate gelatine, it is in summer especially that difficulties arise in its manipulation, and Dr. Vogel avers that by following the advice he gives the operator may fearlessly work the permanent printing process in hot June weather when the thermometer marks 26° Reaumur in the work-rooms. Dr. Vogel's notes are as follows:—

1. The bath for sensitizing is made up of:

Bichromate of potash	4 parts
Water	70 "
Alcohol at 87°	80 "

The solution is kept cool, not by means of ice, but with cold water.

2. The pigmented tissue is dipped in, back uppermost, turned quickly, and the fluid shaken, so that every part of the tissue is thoroughly moistened; it is then taken out. The tissue loses a little of its colour by this mode of operating, but does not run in drying, notwithstanding the heat. After two or three hours the tissue is dry. The alcoholic bichromate bath is only used once.

3. The printed tissue is covered with a one per cent. collodion, and thoroughly dried in the dark; it is then wetted and squeegeed as usual, either upon glass or transfer paper. Undertaken in this way pigment printing is almost as certain in summer as in winter. A grain-like structure is seldom met with; whereas in the case of uncollodionized tissue a grain is nearly always to be remarked in hot weather.

[The coating of the printed carbon tissue with collodion prior to development was proposed in these columns by Mr. Baden Pritchard on the 27th April, and he employs the plan at Woolwich. Not only has it a tendency to check reticulation, but, according to Mr. Pritchard, simplifies the printing process, the washing of the collodion film and soaking of the tissue proceeding simultaneously. The plates are simply waxed, and not collodionized, in this case.—Ed. P.N.]

SECURING VISIBLE PICTURES IN THE CAMERA.

Dr. LIESEGANG writes in the *Moniteur de la Photographie* on this subject. A statement having appeared that M. Willems has succeeded in securing visible images in the camera without development, Dr. Liesegang reminds photographers that he published a method of doing so as far back as 1864, in the *Photographisches Archiv*, and in the *Photographic News* of September 23rd of that year.

To accomplish the result it is necessary to have a good collodion, a silver bath, and a solution of pyrogallie acid (one gramme of acid in two hundred and fifty grammes of water) to which have been added ten grammes of acetic acid. The collodion should have such a consistence and composition as to yield a fine milky film in the silver bath.

The operation is simply as follows. A glass plate is covered with collodion, and plunged into the silver bath in the ordinary manner. The film is taken out as soon as sensitized, and allowed to drain. Then a little of the pyrogallie acid solution is poured into a small vessel, and the film covered with it three or four times. The plate is then put into a dark slide and exposed as usual in the camera; on withdrawal, it will be found that an image ready developed stands revealed upon the film. If a little more vigour is desired, this may be brought about by treating the plate with a further quantity of pyrogallie acid solution, to which a few drops of a solution of nitrate of silver have been added.

Similar results may be secured with a solution of acetate of lead in acetic acid, and with a solution of tannin.

In the same article Dr. Liesegang informs his readers that he describes a method of observing in the camera the actual coming of the image.

LIGHT THROUGH BLUE GLASS.

The chemical action of light in photographic operations, and in promoting vegetation and activity of plant life, is supposed to be very similar, if not identical. The following precise statement of the effect of blue glass on the germination of seeds, given with great precision by a correspondent of the *Scientific American*, will therefore be interesting to photographers.

"Having procured two small tin boxes, and filled them with garden soil, I put into each box six peas (each pea weighing exactly six grains), and six kernels of popcorn, each kernel weighing exactly three grains. One box I covered with strips of blue and common window glass, the proportion of blue to common glass being about four to one. The other box I covered with common glass. I watered the contents of the two boxes once a day with the same amount of water, at the same temperature. At the end of two weeks I removed the earth from the young plants by gentle agitation in water, carefully dried them between sheets of blotting-paper, and weighed them, with the following results:

BLUE GLASS.			COMMON GLASS.		
No.	Corn. grs.	Peas.	No.	Corn. grs.	Peas.
1	0	0	1	19.0	0
2	19.5	37.0	2	23.5	36.5
3	16.5	33.0	3	23.0	34.5
4	16.0	21.5	4	16.0	37.5
5	18.5	31.5	5	26.0	17.0
6	18.5	19.5	6	18.5	0
Total	85.0	142.5	Total	126.0	125.5
Average	17.0	28.5	Average	21.0	31.37
Increase	14.0	22.5	Increase	18.0	25.37

"It will be seen that, after deducting the original weight of each, the average increase of the corn under the blue glass was fourteen grains, while the increase of that

* Failed to germinate.

under common glass was eighteen grains, or four grains in favour of common glass. The average increase in the peas under blue glass is 23.5 grains, while under the common glass it is 25.37 grains, or 2.87 grains in favour of the latter. There was but little difference in the time of germination. The corn under the blue glass was streaked lengthwise of the leaf or blade with deeper and lighter veins of green."

ON THE DEPTH OF PRINTS AND INTENSITY OF NEGATIVES.

BY CAPTAIN ABNEY, R.E., F.R.S.

At intervals during the last three years or more I have been comparing the truth of photography as regards depth of shade with the shades to be found absolutely in nature, and have arrived at results which are worth recording, as they apply to the reproduction of negatives. As regards original negatives, the research does not apply, as the effect of the translation of colour into shades of black and white is almost beyond the power of investigation with the knowledge which we have at present. The time may come, and probably will, when such will be feasible; and though the inclination may be to say, "What's the use of it?" still, like other subjects which, apparently, have no practical bearing, in the end it is probable that such an investigation may be a paving stone in the path which tends to the attainment of some knowledge of still real utility. The subject on which I am at present writing, however, is, I hope, of immediate value both in regard to the object with which I have begun the present article, and also as a means of increasing our knowledge of the means of measuring the effects of different intensities of light.

In a communication made to the Photographic Society in May of 1876 I showed an instrument I had devised for registering the actinism of daylight, and in describing a method of integrating it. I gave a description of a revolving drum by which the reading would be effected. That same revolving drum it is now necessary to describe somewhat more fully, as part of the results obtained depend on a right knowledge of its use (fig. 1).

Fig. 1.

In the figure, which is the same as that which accompanied the paper referred to in the News, some slight additions have been made. On to the revolving cylinder are placed sectors of dead black paper placed on pure white paper. Each sector is accurately cut to exactly the same length, the breadth of each being invariable. Such a disposition of these alternating black and white sectors is shown in the figure. Let B be caused to rotate rapidly by means of A; at a point half way on the length of the cylinder manifestly we shall have half black combined with half white; if a quarter of the way from the bases of the black sectors, there will be three parts black to one white, and so on. By placing a scale (C) divided into twentieths of inches on the top of a rider in which a slit has been cut (in order that only a small portion of the cylinder may be viewed at once), it is evident that any shade of grey may be compared with the shaded grey tint of the revolving cylinder, and the ratio of black to white in the observed grey determined. When chloride of

silver paper is exposed to light the tint it assumes unfortunately possesses a decidedly bluish tint, and a comparison of such paper darkened by light with the shaded grey of the cylinder becomes impracticable, unless an artifice be resorted to. The artifice consists in employing light of some monochromatic colour. If the blackened paper, for instance, be examined in the light of a sodium flame, the blue colour is entirely eliminated, and we have merely the yellow component of the white left in the chloride of silver paper, mingled with a certain proportion of black; similarly the rotating cylinder, when viewed in the same light, would have its gradation formed in "yellow greys," if the expression may be allowed. Now the blue of the darkened silver paper must of necessity be mixed with a proportionate quantity of black, however deep the tint may be; hence to measure the darkening of the paper, it is quite legitimate to compare its yellow grey with those of the cylinder. This might not be the case had it not been proved experimentally that the same values were obtained for any number of differently darkened papers when viewed by various monochromatic colours, and a large part of the experiments were undertaken in order to clear up every doubt on this particular branch of the subject.

I may here parenthetically remark that the place on the cylinder where equal proportions of black and white are mixed does not at all correspond with the spot that would be selected by any unbiassed person who was asked to select a shade which would be a grey intermediate between black and white; the point he would select would be nearly a quarter way from the bases of the black sectors. The intermediate greys are at correspondingly proportional distances. As this part of the subject does not legitimately belong to photography, I merely mention it as curious. An investigation into the subject has been carried out, and will be shortly published.

This rotating cylinder, then, I have employed as my standard of grey, referring all measurement eventually to it. Of course it was necessary to compare the whiteness and the blackness of the papers, and this has been by means of zinc, oxide, and deposited lampblack. All readings have been reduced to these standards. It may, however, be objected that black reflects a certain amount of white light, and this is no doubt the case; but this difficulty is reduced to a minimum where the light falling on the cylinder is so arranged that the reflection there may be passed away from the eye. I have compared the blackness thus obtained with that due to absence of light at the extremity of a long tube, and have found that any error that may exist is so small as to be incapable of affecting the accompanying results, being less than the error that is likely to occur through defective eyesight.

The first experiments that were undertaken were with a view to obtain the different degrees of blackening due to different quantities of exposures and different intensities of light. For the first, exposure was given to uniformly sensitive paper beneath a rotatory wheel, in which the exposure increased in arithmetical progression. It is hardly necessary to describe this piece of apparatus, as it has already been described in the *Philosophical Magazine* and in the columns of the News. Manifestly, by this means, however variable the light might be, the resulting blackening would be due to the mean intensity of light acting during the varying times. The accompanying diagram shows the reading of strips of sensitive paper so exposed when reduced to the proportion of white to black (fig. 2).

The ordinates or vertical lines drawn to meet the curve from the horizontal line measure the amount of white in the darkened paper at each point of its length, unity means the number representing white, being the amount of black mixed with the white, the length of the tint being represented by the length of the scale. Thus at P a point .32 of the total length of the strip, and consequently measuring .32 of the total exposure, the amount of black

In the tint is about .52 of total blackness mixed with .48 of white curves. P, Q, R, and S are curves representing the greys of different strips which have been examined. P was exposed for such a time that the most exposed point was on the verge of bronzing, from which it will be seen that light cannot tint the paper to acquire a depth equal to total black. The other curves, Q, R, and S

Curves showing gradations of shade in chloride of silver paper caused by different exposures.

were exposed for shorter times in the order given, so as to ascertain whether the curves varied in curvature. A reference to the figure will show that within the limits of error of observation and uniformity of paper the curves agree well. For instance, draw horizontal lines from .4, .7 and .85, cutting the curves as far as possible. Now, if the curves are comparable, the abscissae where the curves are cut should be proportional. Comparing Q and S, the abscissae of the former at ordinate .85 is nearly .30, and at .7 is .40; of the latter .61 and .78. The two sets of readings are nearly proportional to one another. Taking one more comparison between the curves P and Q, we have for P, when cut at the heights .42 and .7, .38 and .21 respectively, and for Q .72 and .41, which are nearly proportional. This shows, then, that the curves given by exposures increasing in arithmetical progression are uniform and of definite curvature. A study of these curves shows that the blackening by no means increases according to the length of exposure: that where the exposure is either short or prolonged, the curve is not steep enough; and that for the mean exposure the rate of blackening increases too rapidly.

The application of this will be seen in another portion of the subject.

THE ACTION OF PIGMENTS AND GLASS COLOURS UPON TINTED BROMIDE OF SILVER.

BY PROFESSOR H. VOGEL.*

THE observation made by me that certain substances, like aniline colours, when added to white bromide of silver, are in a position to increase the sensitiveness of the latter for the yellow, red, and green rays of the solar spectrum, has led to the assumption on many sides that the depiction by the camera of oil paintings and other coloured objects in all their natural degrees of light and shade must be possible. Many questions that have recently reached me on the subject have shown me that it would be desirable for me to reiterate once more what I stated two years ago in *Poggendorff's Annalen*.

It is an error much disseminated in the scientific and photographic world, that the chemical action of ordinary pigments, and those employed in glass staining, is analogous to the coloured rays of the solar system. Although everybody knows that the colour of pigments is never pure, still people have no hesitation in assuming that the action of the colour in pigments is the same as that of the

dominant colour which our eyes appreciate. Seebeck, Suckow, A. Vogel, and Doebereiner, all observed that certain chemical actions of light—as, for instance, the formation of muriatic acid from a mixture of chlorine and hydrogen, &c., &c.—do not follow under exposure to red light, but take place when the light comes through blue glass; and the results of modern photography, which reproduces blue very often as white, while green, yellow and red are frequently rendered black, support these observations. I have, however, in a table of colours which I made public, already shown that these reproductions are not always the same; that certain yellow and red pigments—for instance, Naples yellow, light ochre, and lake, as well as certain blues, such as Prussian blue and indigo—only act slightly upon the photographic plate, and, therefore, in an opposite way to the corresponding spectrum colours. These results are easily accounted for by the optical composition of the colours in question.

In a more startling manner still does the contrast between spectrum and pigment colours manifest itself when in the case of spectrum yellow and spectrum red, sensitive bromide and chloride of silver plates are employed for the production of a colour table. When the difference in sensitiveness between the silver salts is taken into consideration, the same results pretty well are secured, whether chloride, bromide, or iodide of silver is employed, with or without the addition of a pigment. That is to say, certain sorts of blue, like ultramarine and cobalt, act in the same way as white; while certain sorts of red and yellow, such as chrome yellow, red lead, and cinnabar, act like black. Even the increased sensitiveness of bromo-iodide of silver for spectrum green has, in the case of short exposures for the depiction of green pigments and green leaves, little of the influence it is given credit for, since a table of colours secured by the aid of iodide collodion gives green quite as vigorously as bromo-iodized collodion under the same circumstances. It is only in the case of long exposures that the favourable working of bromo-iodide of silver for green comes out prominently.

In practice, therefore, it may well be assumed that in the case of wet bromo-iodized plates, the action of coloured pigments depends in the main upon the amount contained in them of spectrum indigo and violet. Only it appears beyond a doubt, that in the employment of a naphthalene chloride of silver plate, which is as sensitive to spectrum-yellow as to spectrum-blue, the action of yellow pigments must be perceptible; and yet it is only the case in a very slight degree. The reason for this is easily found when the relative luminosity of the spectrum colours is taken into consideration, which has hitherto been left out of the calculation when making a comparative estimate of the action of spectrum and pigment colours.

Vierordt has lately specified the relative luminosity of the several parts of the spectrum, and gives the following figures to represent the light intensity of portions of the solar spectrum:—

In red, near line B	2
In orange, near line C	12
In yellow, near line D	76
In yellowish-green, between lines D and E	100
In green, near line E	37
In light-blue, near line F	12.8
In dark blue, near line G	0.8
In violet, near line H	0.07

According to this statement, the proportion of light intensity of the spectrum blue near G to the spectrum yellow near D is almost as 1:100.

No yellow pigment shows, however, such a high light intensity in relation to blue. An intense chrome yellow scarcely appears four times as light as a dull ultramarine, and a plate which is as sensitive for spectrum-yellow as for spectrum-blue (although the first is a hundred times

* *Photographische Mittheilungen*.

more light than the last) will, therefore, in the time by which it would be vigorously marked by the ultramarine, betray but a very weak impression of a neighbouring chrome yellow, which only appears four times as light as the blue. The weak impression should be, indeed, one-twenty-fifth of the other. If, therefore, the action of a yellow pigment is required next to a blue upon a sensitive plate, the latter must either be lit through a suitable yellow glass, by means of which the blue is sufficiently interrupted, or the sensitiveness of the collodion film for yellow must be increased. The results given by tinted chloride of silver lead us to hope that this is possible.

At present but very few colouring matters have been examined. The investigations, however, so far as they have gone, have amply proved the fact of the photographic action of an absorption medium in the sensitive film, and there should be no difficulty in discovering other colouring matters which possess the qualities of absorption in an increased degree. Of course, only such colouring matters are to be employed which are inimical to the preparations used in photographic manipulations.

Correspondence.

PRODUCING COMBINATION PICTURES.

DEAR SIR,—With a view to assist any young beginner who would wish to produce what may be termed a composition picture by means of photography, it may be of service to point out what are the necessary details and rules to enable the pictures to be understood by the public and appreciated by the artist.

First and foremost, the composer must imagine some subject—an incident or occurrence which happened at a certain place, on some particular day, at a certain hour—and all the various details of that occurrence must be vivid in his recollection or imagination. The landscape, the accessories, the figures, their dress, attitudes, and the expression of their countenances must all help to tell the intended meaning of the picture. It is evident that the camera, having no intelligence, cannot imagine anything; therefore any occurrence that has passed cannot be reproduced by it except by obtaining a company of actors to represent it. We know how rare the gift of mimicry and expression of the passions is even in first-rate actors; how, then, can he hope to surmount this difficulty? Should his artistic talent be so excellent as to enable him to design such figures, I should say he had better keep to the brush and let photography alone. It is, in fact, simply a work of supererogation, wasting talent and time; and, after all, the photograph produced is merely a copy of an artist drawing, and subject to contain not only the fault mentioned by Professor Green, but others quite as fatal to its estimation as a work of art. Therefore I should consider what may be termed historical painting as beyond the art of photography. But there are many subjects less pretentious and complicated, which are quite within the powers of photographic art, and would really form more beautiful pictures, for we all know that it is not the multiplicity of adornments that makes anything become beautiful, but their simple, natural, and tasteful arrangement. Allowing that there are subjects which can be executed by pure and simple photographic composition, let us examine the different branches of artistic knowledge required to ensure success, and without which the only sensation the pictures are likely to cause is contempt.

The art of painting is divided into four branches, viz., design, chiaroscuro (or light and shade), colour, and effect; and pictures are estimated by connoisseurs according as they may contain more or less of these qualities; and it is considered that no painter, ancient or modern, was ever pre-eminent in all of them. Design, the first to consider, and certainly without which all the others may be considered useless, comprises perspective, geometry, proportion, and expression. The first object in the education of

an artist is that he shall attain a facility of hand—that is to say, that he shall become, by practice, able with ease and truth to form the outline of anything he may wish to copy or imagine; and it is necessary that the studies shall be of the choicest execution and character, that his hand, his eye, his taste, and manner may be educated at the same time. Photography, giving as it does the design of all objects mechanically, would seem to render the labour unnecessary, but not so if the pupil wishes ever to raise himself above the level of his apparatus, but is content to remain for ever a mere machine. For such I do not write—it would be useless.—I am, dear sir, yours truly,

JAMES MARTIN.

A REFRESHING DRINK FOR THE STUDIO.

DEAR SIR,—During the recent hot weather, when the temperature has averaged 85° and 90° in my studio, a glass of something refreshing has been very acceptable. Being a teetotaler, I did not care for a draught of "Bass" ale, and ginger beer is not to be relied upon for quality, so I made the following:—

Loaf sugar	2 pounds
Tartaric acid	1 ounce
Essence of lemon	30 drops
Essence of almonds	20 "

Dissolve the tartaric acid in two pints of hot water, add the sugar, and lastly the lemon and almond; stir well, cover with a cloth, and leave until cold; put two tablespoonfuls into a tumbler, and fill up with cold water. This drink will be found much more refreshing and more palatable than either ginger beer or lemonade, and as the above ingredients only cost elevenpence halfpenny, and make ten pints of delightful drink, it will be found to cost less than one-half of ginger beer, and I am sure if once tried will be generally used by those that are engaged in close, over-heated, and ill-ventilated dark rooms.—Yours truly, A. J. JAHMAN.

[The addition of a very little bicarbonate of potash to each tumblerful just before drinking will give a wholesome effervescent drink to those who may prefer it.—Ed.]

COMMERCIAL DRY PLATES.

DEAR SIR,—From time to time I have read with interest letters from Captain Turton to the News on commercial dry plates, and some remarks by you on the same subject in your last issue, and I fully agree with him with regard to the great carelessness, in the preparation of commercial plates, which is but too often met with; but, as you say, it is quite impossible to cry down any particular firm or firms in the public journals, owing to the law of libel; and at the same time I do not see how otherwise the object in view can be gained. The annoyance caused by carelessly prepared plates is hardly conceivable, especially when the photographer is in a distant land. In my own case, during the cruise of the *Pandora* last year to the Arctic seas, I almost solely depended upon dry plates (prepared by a well-known firm) for all shore work, and found them invaluable; hardly a plate failed, and they had to pass through the most trying ordeals; but, unfortunately, a large majority were spoiled simply by careless manipulation in their preparation. It was trying in the extreme, after a hard fight to secure some particular view or object of interest, to find, on developing the plate, that it was ruined by comets or streaks, caused by uneven pouring off of the emulsion. In many cases I found the backing had made its way on to the face of the plate, and this alone is enough to spoil any plate. I see no remedy in the matter, unless the makers allow us to have two quality plates, and charge us different prices. Let one column in the price list be for ordinary or carelessly prepared plates, and the other for plates prepared with extra care. We could then, at any rate, be sure of what we were purchasing—at least, I hope so. If I could be certain as to what I was using, I should purchase and use large quantities of commercial

plates; and I have heard many, both amateur and professional photographers, say the same; but as it is, it is mere waste of money and time.

The dry plate makers must be doing as much business as they care to, or else it stands to reason they would give us better samples of their work. With regard to the firm which supplied me in the *Pandora*, I have to say that their plates behaved admirably, with that one fatal exception, namely, that so many were imperfect from careless preparation.—I remain, yours truly,
W. J. A. GRANT.

PRINTING WEAK NEGATIVES.

DEAR SIR,—I presume all photographers will occasionally be unfortunate enough to produce negatives possessing bad printing qualities, arising either through under or over-exposure, or from insufficient intensity, or many other causes. To those who are not already aware of it, I recommend printing all such negatives either in the sunlight or shade (as may best suit the negative) under opal glass, which confers upon the prints a brilliancy and delicacy far superior, and altogether unobtainable through the medium of tissue paper, or any other which I have yet tried. Without further eulogium I leave it, confident that those who give it a trial will find it all I have said.
Jno. WORSNUP.

Proceedings of Societies.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE annual holiday under the auspices of the Edinburgh Photographic Society took place on Thursday, the 12th inst. The arrangements, as usual, were undertaken by the Out-door Committee, and with one or two exceptions the whole of the principal studios in the city were closed.

As was to be expected, in the case of a class which enjoys so few holidays during the summer season, many went off to visit friends on trips of their own, but the great feature of the day was, as usual, the general excursion, which, on this occasion, was to the frequently visited Almond Dell by the canal.

The canal, which in pre-railway times was one of the great highways between Edinburgh and Glasgow, is now almost disused, but still kept in perfect order, and run, at least so far as the beautiful Almond Dell, through a fine tract of country, and is, especially at this season of the year, with its grassy banks and their profusion of wild flowers backed by hedges of hawthorn, dog-rose, and sweet briar, one of the most charming routes by which a journey can be made. The swift boats, so called because they did the journey in twelve hours, have, of course, long ago disappeared, but an ordinary barge, aided by an awning, a few yards of gaily coloured calico, and a liberal display of bunting kindly lent by Messrs. Knox, Samuel, and Dickson, made a very good substitute. The weather, which had been for some days disagreeably wet, looked somewhat threatening, but the photographers have faith in their friend the sun, who has never yet failed to shine on their annual holiday, and so by a little after nine o'clock the whole party were on board. Under the direction of the stewards, distinguished by badges provided by the ever-thoughtful secretary, Mr. Mathison, things were rapidly got into "ship-shape," and at 9:30 the anchor was weighed, or would have been had there been one, but, instead, the order was given for the horses to go. Mr. Kyles, of Portobello, was, as on former occasions, master of ceremonies, and under his active management the stringed band, occupying the stern of the vessel, was kept hard at work, dancing being kept up with much spirit, much to the apparent enjoyment of the younger members of the party. Nor were those who were too old or too lazy to dance left without means of enjoyment, as, during the intervals between the dances, the piano was kept busy accompanying the singers, of which there was a good supply, for both solos and parts. Where all did so well and so willingly it would be invidious to particularise, but we cannot avoid saying that, as on previous excursions, a number of the employees of Messrs. Ross and Fringle gave ample evidence that the encouragement so long given by the firm to the practice of vocal music is still continued.

In addition to the great beauty of the canal banks and the country through which it winds, in its serpentine path, there is another charm to the parties forming such an excursion as that we are now describing, in the fact that the enjoyment of the day

commences with the journey, and lasts during the whole time, while in the more modern method of travelling, especially if the distance be considerable, the excursionists spend, it may be, hours cooped up in parties of eight or ten, in comfortable compartments of railway carriages. The dancing and singing were varied by lunch, and an occasional stoppage at some of the more beautiful places, that a scamper along the banks or across the fields, and a gathering of wild flowers, might be enjoyed; and in this way Almond Dell was reached at about 1:30.

On landing, the party broke up into quiet cosy groups of two, or happy laughing threes or more, and betook themselves, some—especially the twos—to the shady woods, some to riverside to enjoy a "paddle in the burn," some to a quiet lounge on the grass, and some to visit the quaint picturesque old mill in the bottom of the glen, and have a chat with the old miller, or a flirtation with his son. Here the mysteries of the manufacture of oatmeal were fully explained and practically illustrated, much to the delight of many who, although they had all their days been familiar with bannocks and brose, knew little or nothing of how the raw material was produced.

While all this was going on Mr. Annan, or rather his assistant, had been rigging up a dark room, and getting his plates prepared, and by-and-bye the party were assembled, and grouped for a photograph. Only those who have tried it know the difficulty of successfully photographing a large number of excursionists. Fun and frolic being the order of the day, all are as ready to go off into a hearty laugh, and rarely indeed is the funny man absent, or fails to give the required touch. On this occasion, however, all went well, and two plates were exposed under favourable circumstances, at least so far as stillness on the part of the members was concerned, and although the light was not so good as could have been wished, two very fair pictures were obtained.

On the intimation that dinner was ready, a general move was made to the barge, which had rapidly been converted into a comfortable dining-room, and the tables liberally supplied with good things in Mr. Pillan's best style, to which such justice was done as is only seen under similar circumstances.

After dinner, the President, Mr. LESSELLS, who occupied the chair, said that the stewards had wisely arranged that there were to be no toasts, as he had no doubt that all were anxious for yet a little longer to continue the quiet rambles that had apparently been so much enjoyed, or to take part in the games that had been provided. There was, however one toast that ought not to be omitted—"Continued Prosperity to the Edinburgh Photographic Society." Of all the good work that it had done, there was none more to be appreciated than the annual institution of the holiday, and in view of the very happy day that they were spending, and the capital arrangements that under its auspices had been made for their enjoyment, he was sure they would respond heartily to the toast.

Dr. JOHN NICOL said that, although the stewards had left toasts out of the programme, there was one which even they could not object to; one which they themselves had been drinking more than once during the last few days, and which he knew would be, by all present, received with enthusiasm—it was the health of the last new member added to the Society. Most of those present knew that the work of the Secretary was very heavy; but they knew also how industrious, persevering, and willing a secretary Mr. Mathison made, and as he never hinted at a difficulty in getting through it, they would be as much surprised as he (Dr. Nicol) was to learn that he had, a few days ago, gone and appointed an assistant secretary without consulting a single member of the Society. Others might have done as much, and nobody would have thought anything about it; but he was quite sure that those who knew Mr. Mathison best were the most surprised when they heard the good news. Yes, he repeated, it really was good news, as all who had seen her on board to-day must have been satisfied that he had made a good choice. He was quite sure the union would be a happy one, and asked all present to pledge a full bumper to the health and happiness of Mrs. Mathison, their new assistant-secretary. The toast was received as it deserved to be, and followed by the usual song expressive of the good qualities of the happy pair.

After a couple of hours spent in games, for which a number of appliances had been provided, and strolling along the dell, according to the tastes of the members, the barge started on the return journey, and the music and dancing were resumed after tea and a liberal supply of its usual accompaniments had been enjoyed. In consequence of a general disinclination to go home while daylight lasted, the halts were more numerous than in the morning, and the raids on the wild flowers so extensive that, by-and-bye,

the barge looked like a moving flower garden, or fashionable flower show, or musical promenade. Shortly before reaching Edinburgh, Councillor Hay, mounted on the quarter-deck, said that he had been asked to discharge a pleasant duty. He was aware that many wondered wherein lay the cause of the success of the Edinburgh Photographic Society, but he thought that it was not far to seek—it arose altogether from the fact that the office-bearers were the right men in the right places, men who were equally at home in discussing the merits and demerits of the last new process, or organizing and carrying out a social gathering; men not merely able to devise, but not above bearing a hand in the carrying out, of anything that would tend to promote harmony and good fellowship amongst all connected with the Society. "I have, then," he went on to say, "much pleasure in proposing a vote of thanks to the President, Mr. Lessels, for the honour he has conferred on me by being present to-day, and for all that he has done to promote the success of the excursion."

The President, in replying, said that when, on his return from the Continent in November, he found that he had been made president of the Society, he thought the members had made a mistake, and undertook the duties with no little fear. Now, however, he was glad to say that he went to the work with real comfort, everybody seemed to work so smoothly with everybody else that it became really a labour of love, and he was quite sure he spoke for the rest of the office-bearers, as well as for himself, when he said that it gave him much pleasure to see the little that they had to do thoroughly appreciated. As for the excursion of to-day it had been a great success, and he had enjoyed it thoroughly. The evening had been good, so had the dancing, the concert, the day, and the dinner. The latter item, in all such meetings, was an affair of much importance, and he thought the members would not be fully doing their duty unless they accorded a hearty vote of thanks to the parveyor, Mr. Pillans. Those who walked about the town must have been struck from time to time by seeing his name appearing over the door of shop after shop, and could not fail to come to the conclusion that he, at least, was a successful man. I am sure we congratulate Mr. Pillans on his success, knowing, as we do, how thoroughly he deserves it, and that for the best of all reasons—doing the very best he can for his customers.

By this time twilight had deepened into gloom, and while Auld Lang Syne was being sung, the barge was made fast at her destination shortly before ten o'clock, and amidst much hand-shaking and mutual congratulations the gathering was adjourned till July, 1878.

Talk in the Studio.

SMALL POX AND LIGHT.—Dr. Robert Charles Croft, Uxbridge Road, writes:—"Any suggestion which helps to mitigate the effects of this fearful disorder deserves consideration. Will you therefore permit me through your columns to ask those having the care of small-pox patients to try the plan of hanging the windows of the sick chamber with yellow calico: preparing it, in fact, as if for photographic purposes. I don't know to whom the original suggestion is due, or from whom I heard of it, but the results in treatment have been so remarkable that I feel it to be a duty to call attention to it in the most public manner, and therefore beg you to insert this. We have yet a great deal to learn about the actinic properties of light, and we may some day find that the proper management of light will be a great aid in the treatment of disease."

QUEENSLAND POLICE COURT.—Richard Katschbrook, of No. 155, Fleet Street, photographer, and John Baker, of No. 31, Gray's Inn Road, porter, were brought before Mr. Thomas Gabriel on a warrant for selling obscene photographic prints.—Mr. Collette prosecuted, and Mr. Blinson appeared for the prisoners.—Mr. Collette said that the prisoners would be charged with selling indecent photographs, and each with conspiring with the other to sell the prints. Hereupon they had only been able to get at the retail dealers, but they were anxious to reach the wholesale dealers. They had very great difficulty in getting at them, as they only served the trade. They had, however, found on the premises of Katschbrook about 400 negatives of an indecent character. Evidence in support of Mr. Collette's statement having been given, the prisoners were remanded until Friday, and bail was refused.—*Daily News.*

To Correspondents.

F. J. D'ARNA.—Stereotyping is a skilled industry requiring considerable experience for its successful practice. It consists in pouring molten metal into the matrix or mould. The metal is a mixture of lead and antimony. The precise technical points upon which success depends we cannot tell you. Your best plan will be to seek an opportunity to see the process in practical operation. We regret that we cannot help you to an opportunity.

C. L. B.—The loss of tone when the prints are in the fixing bath may be due to many causes; amongst which we may name the following: insufficient depth of tone in the gold bath, and the use of too strong a fixing bath, defective paper. But by far the most common cause is the use of a poor negative, which does not permit the print to be printed sufficiently deeply in the shadows before the face or other lights are over-printed. This is a very common cause; there is not a sufficient body of reduced silver in the blacks to give a rich tone. The print looks very well in the gold bath; but after fixing it is either a drab brown, or slate colour. Use a more vigorous negative, and this difficulty will disappear. Avoid the carbonate of soda in your fixing bath. 2. You did a foolish thing in adding ammonia to your bath, inasmuch as when you subsequently added nitric acid you formed nitrate of ammonia, which is a solvent of oxide of silver, and is an almost certain source of fog. Pour the second bath you made into a flat dish, let it have a few days of strong sunlight, filter, then try it.

STUDIO.—A primary requisite to brilliant tones is a good brilliant negative. With most commercial samples of albumenized paper a forty-grain silver bath is strong enough. For warm purple tones we recommend the acetate bath. To each grain of chloride of gold add thirty grains of acetate of soda and eight ounces of water; use a day or two after mixing. It is not necessary to use warm water in summer. Jackson's dyes will tint the whole picture, lights and shadows alike.

SEXTON.—For art instruction applicable to photography you cannot do better than thoroughly study Robinson's "Pictorial Effect in Photography." It is the only special work devoted to art teaching for photographers. When you have thoroughly mastered, understood, and assimilated the teachings it contains, you may with advantage study other works on art.

PARLAPAR.—The stain to which you refer is most probably due to the albumenized paper having dried irregularly after exciting, drops of the silver solution standing on the surface, instead of the whole draining off regularly and permitting regular drying. It most frequently happens with very highly albumenized paper, and especially if it be kept very dry before exciting, and is sometimes removed by keeping the paper in a moderately damp place a few hours before exciting. The use of a somewhat weaker nitrate bath is sometimes found a remedy. Thanks for photographs of earrings. When such tear-like drops are seen to be forming they should be removed by applying small pieces of blotting-paper, or indeed a sheet of clean blotting-paper may be applied to the whole sensitized sheet, taking care, however, not to remove all the free silver, which would result in a weak flat print.

M. F. B.—The rapid decomposition and turbidity of the intensifying solution of pyro and silver may proceed from two or three causes. It may arise from the addition of insufficient citric acid, it may arise from the use of silver solution from the bath, or from some other silver solution not quite pure; it may arise from the pyrogallol acid being old and not in good condition, it may arise from intensifying in daylight. Probably you may find the source of your trouble in some one of the causes mentioned.

A. B. C.—It appears to be inevitable that you must work with a south light, as it will undoubtedly be desirable to have the thirty feet for the length of your studio. We should build a ridge-roof studio, as you will then secure the north roof light, which will often be valuable. On the south side you will require facilities for receiving the light through tracing linen, or some similar medium for breaking and diffusing the direct sunlight. This may be done permanently by obscuring the glass with a coating of starch, or through tissue paper attached to the glass, but as there are many days in which no direct sunlight occurs, it is scarcely desirable to obscure the glass permanently. Actual experience in the studio will govern your decision in this respect.

ONE ANXIOUS TO EXCEL.—Different photographers use different substances for stopping-out skies for double printing or other purposes. Some use lamp-black ground up with a little size or gum water. Some use the black varnish sold for backing glass positives. Many use a mask of blackened sensitive paper, working close up to the horizon, with a little of any non-actinic water-colour. Any of these plans answer. The use of yellow or black water-colour acutely applied with a camel-hair pencil is the proper mode of filling up the holes in the sky of your negatives. We regret that our duties compel imperative observance of the rule not to answer queries on subjects of this kind by post.

J. C. STAMMERS.—Both are good and contain valuable hints. No. 1 is the most comprehensive, and is really a very valuable work. The price is 2s. 6d. We have pleasure in hearing from you. Several Correspondents in our next.

The Photographic News, July 27, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

THE FRENCH SOCIETY OF ENCOURAGEMENT—ILLUSTRATIONS OF LACE MANUFACTURE—GLASCOLE IN THE GERMAN LABORATORIES—INTENSIFICATION OF CARBON IMAGE.

The French Society of Encouragement.—The French, apparently, do not believe in endowment of research, but they are quite willing to pay for results, and a Society which is termed *Société d'Encouragement pour l'Industrie Nationale à Paris* has published a long programme of what it promises to do for those who successfully solve a series of problems about which philosophers have been posing their heads for some years. We do not think the promises held out in the form of a series of prizes will materially encourage anybody to undertake serious and laborious investigations which he would not otherwise contemplate, any more than a successful investigator would withhold from the world the fruits of his labours should these happen to be of paramount importance. But those who do solve knotty problems in chemistry, agriculture, mechanics, and other important domains, certainly deserve all they can get in the way of prizes and awards, and for this reason the *Société d'Encouragement* should be spoken well of. The *Société* takes time by the forelock in making its arrangements, and in its prospectus talks familiarly of the year 1882, at which date, to be oracular, those of us who are alive will have aged considerably. The *Société* will award fifty-five prizes up to that date, varying from sums of five hundred francs to twelve thousand, or, in other words, from twenty to four hundred and eighty pounds. In all, we are told, the *Société* has 106,000 francs at its disposal (£4,240), and the prizes are to be awarded in different branches. These six are devoted to problems in mechanics, eight to industry, five to agriculture, and two to the fine arts and their application in industry, one of the latter being for the best photo-type process with half-tone. There are, moreover, no less than twenty-four prizes to be awarded for the accomplishment of various matters connected with chemistry. Anybody may compete for prizes, whether inhabitants of *la belle France*, or foreigners, for the *Société d'Encouragement* only occupies itself with general progress, no matter from what side it may come. The prize offered to photographers—or those, rather, who busy themselves with photo-mechanical printing—is one of two thousand francs, and in this case the details of the invention must be lodged at the office of the *Société*, in Paris, before the first of January, 1880. In the words of the prospectus, the prize will be given "to the discoverer of a process which permits of the transformation of a negative, taken from nature, with finely graduated tones, into a block capable of being printed in a printing press with type." The block must give the half-tone and delicacy of a photograph, while at the time it must present no other difficulties in the matter of printing than would be the case in regard to an ordinary wood-cut or cliché from the same. In respect to the other problems connected with chemistry, &c., for which the numerous prizes are to be awarded, we must refer our readers to the prospectus published by the *Société*, which may be obtained by addressing the Secretary, at the Rue de Rennes No. 44, Paris. The only award relating to photographic work is the one we have specified.

Illustrations of Lace Manufacture.—Photography in book illustration is always valuable, since it presents us with a truthful representation which other arts do not always afford; and when, moreover, the subject is suitable for photographic illustration, then the importance of the book is increased many fold. In a series of works which have lately appeared in several countries on the subject of lace manufacture, this is especially the case. Our readers may remember that we have already spoken in these columns of the use made of photography in connection with the sewing

of lace, the work girls being supplied with a representation of a real bit of the material, instead of simply a bald pattern. The hand-made lace is made in small quantities by different hands, and then fitted and stitched together subsequently into a piece of some size. Where several hands, differing from each other not only in skill, but in other qualities also, are thus engaged on the integral parts of a whole, it is very unlikely that these different parts will accurately resemble one another, particularly as the girls have simply a rough outline sketch to guide them, which is widely different from the lace itself when finished. There is, in fact, much left to the discretion of the girls, and as they are not all guided by one mind, there must naturally be considerable discrepancies in the work, even when this is pieced together with tact and judgment. The recent introduction of photography in lace warehouses has, therefore, done much to equalise the work and render it more uniform than it used to be. Instead of a pattern roughly limned on paper, each worker has now a photograph given her, which is to the eye, to all intents and purposes, a bit of lace, since the pattern is taken from an exceptionally nice piece of work, prepared on purpose by the most skilled hand in the factory. Furnished with this, the girls have no difficulty in keeping to the pattern, and making all the pieces identical as regards the stitching and the intervals in the open work. Publishers have not been long in finding out how useful books upon lace manufacture might be made with illustrations of a similar character, and the consequence is that during the past year or two a collection of such books has been brought out. Thus we have one issued at Leipzig which goes methodically into all sorts of fancy needlework; another at Paris, quite as exhaustive, apparently, and entitled *La dentelle, histoire, description, fabrication, bibliographie*; a third appears in Austria, at Vienna, under the title of *Spitzen Album*, which contains a description and illustration of old point lace in the Imperial Museums; and finally we have a volume in London upon *Ancient Needle-point and Pillow-lace*.

Glascoole in German Laboratories.—The employment of glass-wool—or, in other words, very fine spun glass—for laboratory purposes, seems to be gaining ground among German photographers. No doubt, for the filtration of collodion, as also in the case of acids and strongly acid solutions, glass-wool will be found convenient, and where before chemists were wont to use asbestos and powdered glass. The manufacture of the new filtering medium has consequently been warmly taken up, and we find that it may be now purchased at no very exorbitant rate. Glass-wool is very light, too, and may be used over and over again, for it is easily washed and freed from foreign matter attaching to it. These qualities are prepared, it seems, but only the first is recommended for photographic use, since both the filtration of collodion and the silver bath, for which it would be mostly used with us, are delicate operations, and require to be well and carefully performed. The glass-wool should, therefore, be of the purest and finest quality—such as is sold at the rate of a mark or shilling per five grammes, or at fifty-five shillings a pound. Coarser qualities of the material for the use of manufacturing chemists are to be had, charged for at half this rate.

Intensification of Carbon Images.—In respect to the communication recently published by M. Stefanowski upon intensifying carbon images,* exception has been taken at the Vienna Photographic Society, by Dr. Eder, on several points. Dr. Eder's name is well known to our readers as one who has made an exhaustive study, in connexion with Captain Toth, of lead intensifiers. He thinks that many of the intensifiers referred to by M. Stefanowski will not yield permanently tinted carbon prints, and that while they may be suitable for diapositives, where the tint is only temporarily required for producing negatives, it will not be well to employ some of the intensifiers where pictures are required to be kept; particularly the colouring matters of

* See PHOTOGRAPHIC NEWS, 30th June.

organic origin, as also those which are formed by sulphur in combination with iron, nickel, or cobalt, are not to be relied upon. It is the same with images in which the blue cyanide compounds are formed. Dr. Eder thinks it well to publish this warning, which photographers will do well to bear in mind.

SKYLIGHTS AND SIDELIGHTS.

BY R. J. CHUTE.*

THE light is the most important feature of a photographic gallery, and yet it is the one in which the most mistakes are made in construction. Too often, however, the photographer is the victim of circumstances, in that he is obliged to conform to some condition of the building, such as its situation, its surroundings, &c., which he knows to be unfavourable for his light, and which will put a severe tax upon his skill to ensure success. Then again there are others who go to work with everything in their own hands, and construct the worst kind of a light that human ingenuity can devise.

But photographers are coming to a better understanding in regard to lights, and many enquiries during the past spring show them ready to accept what has been proven to be the best.

A photographer is sometimes deterred from locating in business because he cannot find a light or locality to suit him. This is well; it is better to be cautious than reckless, and yet there is not much risk if one has the ability to adapt himself to circumstances. In lieu of a skylight a high sidelight may be used till a good skylight can be secured or built.

Having had some recent experience in fitting and working a high sidelight, I was much pleased with the results secured by it. It was about twelve feet square, and situated due north. I ran a blue, opaque curtain across the bottom so that the top of it was about four and a half feet from the floor. Above this were two breadths of white muslin curtains, running on wires so as to be readily adjusted to the requirements of the light or sitter. On the shadow side I placed a screen of a light neutral tint, which being moved near or far from the subject produced the desired effect. In addition I ran a white curtain on a wire across this side screen, at about the height of the sitter's head, for the purpose of lighting up dark or tanned faces. This light for single heads I found to work remarkably well, producing negatives as well lighted and of as fine modelling as could be produced under most of the combination lights.

But, remember, I do not advocate such a light for all work, or advise any one to adopt it for a permanency; but photographers are often out of business, or looking for locations, and as sidelights are more readily found and fitted than skylights, it would often be better to locate temporarily with the former, till a suitable light could be found or built, than do nothing.

The combination, or top and sidelight, is the best adapted for all work, and no photographer should think of locating permanently without the very best light he can secure. The most common error in skylights is the height. In many cases this is from choice, as high lights have their advocates, who sustain them from theory rather than from practice; in many others it is from necessity arising from the construction of the building, which cannot be altered. But a photographer had better reject a location altogether than accept it with an unfavourable light, for success depends upon that more than upon any other part of the gallery.

The loss of light, which is the principal objection to a high skylight, may be compensated for by making the light proportionately larger. As, for instance, suppose a light sixteen feet square and eight feet high above the

head of the sitter; the latter would receive the same amount of light above an angle of forty-five degrees as under a light twenty-four feet square and twelve feet high; but place the sixteen feet light at the height of twelve feet, and there will be a loss of fifty per cent. in the amount of light admitted to the sitter.

Thus it is clearly to be seen, as all practice proves, that a high light will work slow compared with a low light of the same size. But as there are many high lights in use, the successful working of them depends much upon the arrangement of screens and the methods of operating. I have recently had occasion to work under one of these high lights, and a little talk about it may not be without interest. It is a combination top and sidelight, but the latter is so obstructed by a building opposite that it is mostly a top light. The lowest part of the top light is fifteen feet from the floor, and the highest more than twenty. To make this manageable I placed a series of curtains of drab cambric just high enough to clear the backgrounds. They are hung on wires running across the room, and are low enough to be easily manipulated with a short rod, thereby dispensing with all cords and pulleys.

On the side light a curtain of the same drab material covers about four feet of the lower portion of the light, and above that are two breadths of curtains which extend high enough to meet the curtains on the top. Just above the top curtains I arranged several frames covered with white tissue paper. These are for use when the sun shines, and may be slid away from under the light when not wanted.

With this arrangement fine effects may be secured, though it is difficult to get quick sittings, even by opening the full light. It is only one more argument against high lights, and I trust that photographers who may contemplate reconstructing or building a light may learn the lesson beforehand, and not, when it is too late, regret that they build their lights so high.

LIGHTING FOR STEREOSCOPIC PORTRAITS.

DR. VOGEL, in his letter to our Philadelphia contemporary, gives some interesting remarks by Herr Goltzsch on the subject of lighting the model for stereoscopic portraiture. He says:—

"What we find passable, or even beautiful, in plain photographs, will have a disturbing and strange effect in stereoscopes, and this circumstance occurs much more in portraits than in landscapes or architectural pictures. Up to this time the portrait stereos were taken with the same lighting as common pictures. For the latter a heavy contrast of light and shade is necessary to bring out their forms; but this is to be omitted in stereoscopes of near subjects as well as portraits. Therefore it is improper to light in the same manner as though we intend to make effective cartes-de-visite. The deep dark shades do not add to their effect in the stereoscope; but, on the contrary, pictures which seem to the eye flat and monotonous, are often very effective in the stereoscope. For this reason it should be tried to take portrait stereos in full light, with but very little shade. It is a fact, that portrait stereoscope pictures have received, so far, but little approbation, not only in Europe, but also in America, though it seems to me there are made more portrait stereos there than here. If the matter were treated in the proper manner, it would merit the approbation of the public in a greater degree; but I recommend the use of lenses with a short focus, especially when half-length pictures are to be taken, or they will show excessive plasticity, so that the head often seems to be several feet in front of the body. Take lenses of eight to nine inches (equivalent focus), the centre points of which are not farther from each other than two-and-a-half inches."

* Philadelphia Photographer.

LACONICS.

BY W. HEIGHWAY.

Do not waste leisure hours—*Practise!* Study what you have heard, read, or seen, in lighting, posing, and manipulation, and work out the lessons.

Would you acquire information? *Read!* Would you progress in art? *READ!!* Would you make money? *READ!!!*

Study the work of others, and try to understand in what it is good or bad; and see how its errors are to be avoided, or its beauties imitated.

Servile copying requires no more ability than allowing your neighbour to work out a sum, and then cribbing the answer.

Govern your retouching pencil, or it will make a slave of you.

Never say of your work, "Oh! it's good enough for the price."

We should, in matters of taste, be *above* the general public, and strive to raise them, rather than sink to a vulgar level.

The educated eye alone can see effective points and defects in the sitter. Strive by observation and study to acquire this valuable power.

Truth should be the chief feature of a portrait. Flattery should not be resorted to—even with your sweetheart; it is inartistic!

Photography and truth are united by art.

You cannot do good work until you find out you can do bad. It is difficult to make a donkey go straight, because—he is an ass.

Some photographers are so conceited they cannot see the blemishes in their own work, any more than they can see beauties in their neighbour's. How can they expect ever to excel?

Take care of your health—resurrections don't take place now-a-days.

Keep your dark room well ventilated—and, too, keep it clean: it is healthy for you and for your work.

Too often the lighting of the sitter and the good character of the negative are sacrificed to the thought that the retouching will remedy all defects. It is very like neglecting to get out of the way of a homicidal cart, because you believe the doctor will be able to cure the broken limb.

So many negatives are spoiled by over-retouching, one is almost inclined to say, do not retouch at all.

When things work badly, don't blame the bath, the developer, the camera, and the sitter: try a little more carefulness.

When matters get very trying, lay on your sweetest smile, and try to charm them into better ways.

If the bath is pinholing your plates, you may sometimes cheat it by tilting the bath forward on the immersion of the plate, so that the collodion surface faces downward.

When I come across a man who says he can never see any use in books on photography, and that he never learnt anything yet from them, I try to discover what he knows. *It is never worth the search.*

theless, as it may be found of use in many applications, and capable of doing good service in certain circumstances, I have here set down in a few words how a good result may be obtained with little difficulty.

When it is a question of producing a typographical block, a zinc or copper plate is taken from three to five millimetres in thickness. This is grained, and while warm covered with a light coating of wax. Upon the wax a carbon tissue is developed in the ordinary way, and further treated with alum, and dried. The plate is then immersed in benzole, or any other solvent of wax, and in this way all parts of the metal surface are bared except those covered by the carbon image. These bare portions are to be acted upon with acid. The carbon image, in truth, only acts as a covering to the wax, and prevents this from being dissolved away by the benzole where the image is to be; the acid etches the metal afterwards wherever the latter is not covered up.

To obtain type blocks an ordinary negative cliché is taken, which gives, after etching with acid, the image in relief, and in this state it may be printed from in an ordinary press. If, on the contrary, a positive cliché is made use of, you secure a block which can only be printed in the same way as an engraved plate, the image produced being an *intaglio*. It is possible, however, to secure a plate for printing in an engraver's press, with the aid of an ordinary negative cliché, by having recourse to another method of proceeding. This consists in recovering the zinc plate bearing the image with a deposit of copper by means of the electrotype process, and removing the pigment afterwards with hypo-chlorite of lime and boiling water, and afterwards the wax with benzole. Finally, the plate thus prepared is etched with acid, the aid of a battery being recommended to bring about a more perfect result. In this case the thin film of copper which has been deposited resists the action of acid, which attacks the zinc, however, with considerable vigour. To succeed well with the process, it is necessary to have clichés of a very clear nature, in which the blacks are very opaque, and the whites free from fog, while the carbon tissue must not have been exposed to the light in any way, for otherwise a slight insoluble film will be formed over the plate, which will materially interfere with the perfection of the result.

This plan of operating has much in common with that described by Mürkl, and which was published in this journal (the *Moniteur de la Photographie*) in October, 1876; but in that case the employment of asphalt dissolved in benzole is recommended for making the reserves of the plate prior to the development upon it of the carbon image. I find that wax is much better for the purpose, for while I have frequently had instances of failure with asphalt, I have never met with defects when wax has been used for treating the zinc plate in the first instance.

I am now engaged in further studying the subject, with a view, if possible, of securing photo-engravings or phototypes having half-tones. My experiments are being conducted with gelatine, and I trust by means of this substance to secure photographs from a press, and printed in greasy ink, and with the same gradations as those secured with silver salts. I shall not fail to make public my results, if they should turn out preferable.

A SIMPLE PHOTO-GRVURE PROCESS FOR SECURING BLOCKS FOR PRINTING IN A TYPE-PRESS.

BY ERNEST BOIVIN.*

THE shortcoming of this process, like that of many other methods of the same character, is to be found in the fact that it will not permit of the reproducing of the half-tones of a negative. It is only capable of employment in the case of clichés taken from engravings or designs executed in line, &c., where only blacks and whites come into play. Never-

MODE OF REDUCING NITRATE OF SILVER IN WASTE SOLUTIONS.

BY F. FLAMENT.*

THE collection of argentiferous compounds from waste solutions has been an object of study with me for some time past. In my essays, which were rendered doubly interesting on account of the beautiful reactions to which they gave place, I desired more especially to exclude the use of flower sulphur, which is so generally employed, but which, on

* *Moniteur de la Photographie.** *Moniteur de la Photographie.*

account of its disagreeable odour, &c., is well left alone. The method I am about to describe renders one altogether independent of sulphur compounds, a desideratum of some importance, since the silver afterwards recovered is more pure.

The nitrate of silver in the disused baths and other solution is first of all turned into chloride. To do this, the liquids are put into an earthenware vessel competent to hold about double their volume, and I then add enough hydrochloric acid in sufficient quantity until a precipitate is no longer formed. After standing for some time, the upper portion of the liquid is poured off, and the remainder is treated anew with the same acid, but not quite so strong—that is to say, with ordinary commercial muriatic acid. The chloride of silver which has been deposited by this means is then washed until every trace of acid has disappeared, and afterwards pressed between sheets of filter paper, to facilitate its desiccation.

This chloride of silver is intimately mixed with carbonate of soda in the proportion of:

Chloride of silver, well dried	...	1 part
Carbonate of soda	2 parts

The mixture is filled into a crucible, and placed in a suitable furnace, and as soon as the mass is in a state of fusion, some bits of charcoal are thrown into it. Ten minutes afterwards the crucible is withdrawn from the fire, and on cooling there will be found at the bottom of the utensil a button or ingot of pure metallic silver.

In remote localities, where it is impossible to obtain virgin silver, I treat nitrate of silver in this way which I have previously obtained by dissolving silver coin in nitric acid. By treating a solution of this kind with hydrochloric acid, chloride of silver is precipitated, and I obtain in the end a pure metal free from the oxides of copper, which silver coins, as a rule, contain in the shape of alloy. It is true that these oxides do not dissolve in water, and consequently remain on the filter paper, but they are nevertheless in the mass, and hinder weighing accurately. In other words, pure nitrate of silver could not be secured by simply dissolving silver coins in nitric acid, and allowing the nitrate to crystallize out.

[We need scarcely warn our readers that in this country it is a criminal act to employ the coinage of this country in this way, or, indeed, to deface it in any manner.—Ed. P.N.]

THE LICHTDRUCK PROCESS.

BY M. COMTE LUDOVICO DE COURTEN.*

M. DE COURTEN employs patent plate glass from five to six millimetres thick, and he cleans it in the following manner. If the glass is new it is cleaned in the same way as a photographic plate, and rubbed with alcohol prior to use. If an old plate is to be cleaned, it is first of all cleaned with nitric acid, or caustic potash dissolved in hot water. Every trace of grease repels liquid, and causes fissures and rising of the film, and gives rise also to air-bubbles.

Solution for the first preparation of the plates.

No. 1.—Best gelatine	...	10 grammes
Cold distilled water for swelling the gelatine	...	250 "
No. 2.—Bichromate of potash	...	10 "
Distilled water	...	250 "

The two glass vessels which contain these mixtures are placed in a water-bath maintained at a temperature of not more than 50° Centigrade. When the solutions are complete, the gelatine is filtered through fine linen into another vessel also standing on the water bath, and then the bichromate solution is added, and the mixture allowed

to cool somewhat. Hereupon is gradually added 250 cubic centimetres of albumen made from fresh eggs, beaten to a froth, and decanted. It is filtered through paper, the liquid being maintained at 35° C. the while, and allowed to stand for an hour on the water-bath, the temperature of which should not be allowed to exceed 40° C. The plates are carefully covered with this solution, the former being placed in a horizontal position while the liquid is poured upon them. To make the mixture cover the plate perfectly a strip of clean paper may be used, breathing on the glass also facilitating the operation; and finally the superfluous liquid is permitted to run off at one of the corners. The drying of the plate takes place in the dark.

As soon as the first film of bichromated gelatine is dry, it is covered with a level piece of board covered with black velvet, and exposed to light from behind, the light acting upon the sensitive film through the thickness of the glass. By this operation the glass is made to attach itself more firmly to the glass surface. The exposure to light is continued until the film assumes a dark brown colour, or until a strip of paper dipped into the sensitive mixture shows 10° under Vogel's photometer.

After this exposure the plate is thoroughly washed in a zinc or enamelled iron trough until all the yellow bichromate is removed, and the film appears of a matt white. Then the plate is dried and preserved in a locality free from moisture. They will remain in a good condition for some time.

The second film may now be applied. The composition of this second preparation is rather elaborate, the following solutions being required:—

1.—Gelatine	...	45 grammes
Distilled water for swelling	...	360 cub. cents.
2.—Bichromate of potash	...	7.5 grammes
Bichromate of ammonia	...	7.5 "
Distilled water	...	120 cub. cents.

Two separate solutions are made at a mild temperature.

3.—Isinglass cut into strips	...	22 grammes
Distilled water	...	80 cub. cents.

The water in this case must be warmed to 90° C. in order that the isinglass may be dissolved.

When the solutions are prepared, they are mixed together and filtered through paper into a glass vessel standing on a water-bath heated to 50-60° C. At this temperature the mixed liquid is allowed to stand for about an hour and a-half, so that the operator may be assured that the liquids have properly united. The filtration of the liquid must take place by the aid of warmed filters, for without this precaution the liquids will become set, and the operation go on but very slowly. All precautions which were taken in the case of the first film must also be employed in manipulating the second. The drying cupboard must be warmed previously, and each plate, before being coated, should have a temperature of from 40° to 50° C. The second film is applied to the surface of the first. Two hours are required for the drying of the second film at a temperature of from 55° to 65° C. When dry the film appears yellow upon the plate; it should be matt and very even. The plates so prepared will remain in good condition for two or three days, if only properly kept in a cool place, in absolute darkness, and protected from moisture.

The next step is to print the film in a frame. In the first place there is laid upon the glass plate of an ordinary printing frame a piece of black paper in the form of a mask, the opening of which is of the form and size of the cliché to be printed. The negative is then placed upon the mask, and the prepared plate laid on the negative. It should be remarked that the negative must be a reversed one. The way to produce such a negative is well known. Either an ordinary negative is stripped from the glass by means of gelatine, or the cliché is taken by the aid of a mirror, or in any other way that gives a reversed image.

* Abridged from the *Moniteur de la Photographie*.

As already stated, an ordinary printing frame may be employed, but in this case it is well to employ wedges under the cross-piece instead of springs, so as to ensure more pressure and better contact. To cut off all light from the back a black cloth is laid over the glass plate.

The coming and progress of the picture may be watched from the back; all details must appear in brown. The plate is then taken out of the frame, and undergoes a lengthened washing to remove the bichromate. On drying, it is next brought into the press, and a sheet of paper put under it, so that the inking up of the image may be the better watched. At this point begins the work of the lithographer, and better than all instruction is a practical demonstration at a lithographic establishment. The preparation of the plate for printing is, however, a little different to that of a lithographic stone. Before the plate is inked up for the first time it is moistened for the space of a minute with cold water by the aid of a sponge. Afterwards the moistening operation need not last more than from twelve to fifteen seconds. The plate is then dried off by the aid of a soft linen rag, and again inked up.

The inking of the image is a very difficult matter, which not only requires very great attention, but also considerable experience and study.

EFFECT OF ACIDS AND ALKALIES ON GLASS.

In answer to a correspondent of our Philadelphia contemporary, Mr. Thomas Gaffield, whose communications to our pages, as a manufacturer of glass, our readers remember, gives the following hints as to the action of acids and alkalies on the surface of glass: the information will be useful to our readers.

"In a general way we may answer that no alkali has any effect on well-made glass, and no acid, except hydrofluoric acid, which is consequently the only one which can be used for etching purposes. In our chemical laboratories all acids and alkalies are kept in glass bottles, except the hydrofluoric acid, which requires vessels of lead or gutta-percha. But if glass be made in an imperfect manner, either from too great haste in melting, or from an excess of alkali in its composition, the action of the atmosphere alone, in connection with the affinity of alkalies for moisture, causes an efflorescence of the uncombined soda or potash, sometimes furrowing the surface in an infinitesimal manner, creating an iridescence, and sometimes disintegrating it in such a way as to produce all the appearance of ground glass.

"The natural surface of any glass is undoubtedly its strongest portion, and when that is removed, by grinding on the wheel or by hydrofluoric acid, the strength is materially diminished. Now, if the surface of an inferior glass is disturbed in any degree by the action of the atmosphere, as above indicated, or by contact with alkalies or acids, as suggested by your correspondent, just in that degree will it be weakened in strength. I suppose that most of the sheet glass sold for negatives is strong and well made, and not seriously affected by the removal of the films and subsequent cleansing. Of course, there are some exceptions, as it is difficult to achieve perfection in any manufacture, and it would seem that your correspondent has found by experience that his old negative glasses break more easily than new ones that have never been used, and, therefore, may not be of the best kind.

"It may be interesting to remind your readers that cases have occurred where the removal of collodion or gelatine films has carried away also a thin film of the surface of the glass itself. This, of course, would destroy or seriously deteriorate its strength and value.

"It would be quite interesting to hear of the experience of other photographers on the point of the strength of negative glasses after being in use several years. It is possible that a multiplication of experiments, and a scientific examination of the subject, may prove that a long exposure to sun-

light may not only change the colour of our glasses, but involve such a physical change in the molecular structure of the glass as to materially weaken its strength. It may be such a change as this, rather than the use of acids and alkalies, which weakened the glass of your correspondent after long usage and exposure to sunlight in making his negatives. This idea, however, is only a momentary thought of the writer, which is not to our knowledge suggested in any treatise on glass, and may not, after careful examination, be found to be sustained by any facts or reasonable theories."

A FEW WORDS ABOUT BURNISHING.*

To condensation of water contained in the alcohol need to heat the burnisher, more than to anything else, we attribute the trouble in burnishing. Another cause of difficulty in burnishing is the use of alum in any form, either in the silver bath or the washing after toning. We never use it, but I know some who do, who always calculate on fourteen prints to the dozen, expecting to spoil at least two of them in the burnisher.

We claim nothing original as a lubricator. At present we have got good effects by making a pasty mass of fine white wax and ether; this we spread on the woolly side of longnap Canton flannel, and rub the picture with it. Care must be taken not to have too much on the cloth, else some will get on the back of the card and stain it. A cloth properly prepared will lubricate a great number of prints, probably two hundred. Another very good plan is to procure a piece of white soap (glycerine or coconut oil soap); rub a piece of Canton flannel on this until it is coated, then rub the print evenly, renewing the soap on the cloth as required. Another way is to dissolve wax in alcohol, and apply with a broad flat camel's hair brush. The alcohol dissolves very little wax, but very little is required. We have done very fine burnishing with alcohol and glycerine applied with a flat brush. The formula is—

Alcohol	8 ounces
Glycerine	2 drachms
Essence wintergreen	40 drops.

This gives a pleasant perfume to the cards, yet not offensively strong.

The temperature of the burnisher has a great deal to do with the effect. Try a print when the planisher has just reached boiling heat, and the feed roll is comparatively cold; then let the heat be increased as high as possible without blistering the print, run a print through a few times, and "compare effects." That is the true test.

If kerosene is used as a heater, it is difficult to get a proper degree of heat, and there is great danger of smoking. If alcohol is used, "sweating" is certain, except in extremely warm weather. Before applying the alcohol lamp, see that the planisher is lowered at least an eighth of an inch; a quarter of an inch is better. It must be sufficient to prevent the water, which condenses on the feed roll, from touching the polished surface of the planisher, because wherever it does so a spot is produced with a rough edge, which must be polished off to avoid scratching the print. To polish, take a piece of soft pine, about an inch wide, and thin enough to run between the planisher and feed roll; pour on a few drops of olive oil, sprinkle with flour of emery, and rub the planisher lengthwise, from end to end. Two things are important: it must be flour of emery, and the stroke must not be short, but must go the full length of the planisher. Wipe clean with a cotton cloth, and with or without a lubricator you may go on with your burnishing fearlessly, unless you have used an acid in the previous manipulation, in which case a lubricator is an absolute necessity. No amount of burnishing will make dull, mealy, or half washed prints look well.

THE FORTHCOMING PHOTOGRAPHIC EXHIBITION.

THE full details of arrangements for the next Exhibition of the Photographic Society are now issued, and they will, we doubt not, be found satisfactory to every one concerned. The Exhibition will, as we have before announced, be opened on the evening of Tuesday, the ninth of October next. There will be a conversation as heretofore, and the council have abandoned the plan, adopted on occasion of the last two or three soirees, which was found to work unsatisfactorily, of requiring what is known as "evening dress." "Morning dress" is on this occasion requested. We may, perhaps, remark in passing, that the edict for evening dress, which gave offence to some, and was inconvenient to many, was rendered desirable, we understand, from advantage having been taken of the freedom which prevailed at some of the earlier informal soirees, by some thoughtless persons, to present themselves in absolute working dress direct from the printing or operating room. This should be avoided.

Contributions must be sent in, it will be seen, not later than the second of October. The edict of the last year, which was found to work unsatisfactorily, prohibiting the attachment of a name to a picture, is not repeated this year. Nothing contributes more, we think, to the comfort of visitors than a neatly written label containing the title of the picture and name of the artist, so that these elements of information may be obtained at once without consulting the catalogue at every moment. The medals, it will be seen, are all of bronze, the distinctions of honorary value attaching to the use of different medals being avoided. The constitution of the jury this year will give the awards especial value, as the value of such awards is naturally increased by the character of the judges by whom such honours are dispensed. Besides three members of the executive of the Society, two distinguished Royal Academicians have consented to act, and two of the private members of the Society amongst the most distinguished by artistic culture and ability. We heartily hope the Exhibition will be worthy of the occasion, and we urge all our readers who can to contribute to its excellence and success.

The following are the arrangements according to the official programme just issued:—

The Exhibition of the Society will be held at the Gallery of the Society of Painters in Water Colours, 5, Pall Mall East, London, S.W.

It will be inaugurated by a conversation, open to members and their friends, at eight p.m. on Tuesday evening, the 9th of

October (morning dress). It will remain open daily (Sundays excepted), from nine a.m. till dusk, until the 15th of November. The evenings during which the Exhibition will be open will be announced subsequently.

Members will be supplied with tickets to admit their friends. An admission fee will be charged to all not provided with tickets.

Pictures for exhibition must be forwarded (carriage paid) to the Gallery, 5, Pall Mall East, London, S.W., addressed to the Secretary of the Photographic Society, so that they may be received not later than Tuesday, the 2nd of October, and accompanied by a letter of advice.

Each frame should have the artist's name and the subject written upon a label in front, capable of being easily detached as soon as the catalogue has been made out. No other marks should appear on the picture.

No picture in an Oxford frame will be admitted.

No picture previously exhibited in London will be admitted.

No coloured photograph will be admitted.

Not more than one frame of a dozen cart-de-visite or cabinet pictures can be received from any intending exhibitor.

No pictures whatever can be received after 2nd October, the day fixed for their reception.

A committee of selection will have the power of rejecting any pictures forwarded.

Bronze medals will be awarded as follows:—Two medals for those pictures which, in the opinion of the jury, shall display the greatest general excellence; two medals for the best landscape, ten by eight inches and under, and for the best above ten by eight inches, two medals for the best portrait, twelve by ten inches and under, and for the best above twelve by ten inches; two medals for the best single figure study, twelve by ten inches and under, and for the best above twelve by ten inches; two medals for the best enlargement untouched, and for the best enlargement and negative, both being the work of the exhibitor; two medals for the best genre pictures; two medals for the best photo-mechanical prints; one medal for the best study from animal life; two medals for the best instantaneous pictures; two medals for the best stereo six transparencies; one medal for the best frame of dry plate photographs; one medal for the best micro-photograph; one medal for the best specimen of surface printing from metal; one medal for apparatus. Three medals will be placed at the disposal of the jury for any novelty or other form of excellence in process or result.

The awards will be decided by a jury consisting of seven gentlemen: the President of the Society, two members of council, two members of the Society not being members of council, two artists of reputation (namely—E. W. Cooke, R.A.; Sir J. Gilbert, R.A., President of Society of Painters in Water Colours); James Glaisher, F.R.S., &c., President; Captain Abney, R.E., F.R.S.; T. S. Davis, Frederick Piercy, Robert Faulkner.

No awards will be made when the works in competition are not in the opinion of the jury of sufficient merit.

The competition will be open to all photographers, whether members of the Society or not, and foreign photographers are especially invited to contribute their works.—H. BADEN PRITCHARD, Hon. Secretary.

PHOTOGRAPHY IN NEW ZEALAND.

It not unfrequently happens that we have enquiries from photographers contemplating emigration, asking us for information as to the probable chances of employment as photographers in different colonies. An old correspondent of the NEWS, and a thoroughly experienced photographer, has recently emigrated to New Zealand, and sends us his impressions of photographic prospects in that colony, which are not, as will be seen from the following extracts from his letter, by any means favourable. Mr. Cherrill, it will be remembered, recently wrote from the same colony in a more hopeful strain; but the difference in the aims of the two writers must be noted. Mr. Cherrill went with the view of commencing business, and with capital enough to enable him to do so. Our present correspondent went out in the hope of securing fairly remunerative employment in some studio; in which hitherto he has failed. He says, writing from Dunedin:—

"I must confess I am much disappointed, as I have been

here now nearly five months, and have not succeeded in obtaining employment of any kind. I think some time last year you had an enquiry as to the chance of a photographer coming out here meeting with remunerative employment as an assistant. Should you be again asked your opinion on such a speculative movement, I think the best thing you can do would be simply to give Punch's celebrated answer to persons about to marry—*Don't!* as our kind are a drug in the market. Here is my experience to wit; and there is another who sailed from London just a month previously, after upwards of two months' residence here, finding there was no chance of succeeding, returned in the same ship that brought him out.

"The scenery about this part of the colony (the southern end) is magnificent for the painter, but the extraordinary darkness of the green of the herbage must mar any successful attempt at photographing the open landscape, although I have seen many beautiful pictures of the rocky fissures in the high cliffs, and which we call sounds here.

"In this city, of under twenty thousand inhabitants, there are seven or eight photographic establishments for portraiture, of which those of Messrs. Clifford and Morris and Mr. Burton (one of the Burtons of Leicester) take the lead. The pictures from the first-named establishment seem to please the public most, from the negatives being most carefully and *very extensively* retouched; and as this city is mostly peopled by the canny Scot (in fact, this province of Otago was founded by people north of the Tweed), red locks and freckles are very abundant, which you know do not look well in photography.

"Humbly has not been left at home, as I was much amused the other day by an acquaintance calling my attention to a new frame of specimens hung out to public view at a gallery entrance, and which were labelled as the newest and greatest novelty (photographic) of the age. You will think how much I was amused at this puff when, on going to examine these wonderful productions, I found they were nothing but specimens printed from very inferior negatives by our comparatively old and ancient process on opal glass.

"I brought with me my collection of photographs, those which you kindly sent me, as well as examples of Robinson, Lewis, Slingsby, Restall, and other good men, and I am much flattered by being told there is nothing to equal them in the colony.

"Mr. Morris, who is certainly the A1, has requested that I will sit to him, in order that I may send a specimen of his work to Abel Lewis, to show how gratified he was by seeing the pictures I have by Mr. L.

"Some two months since I replied to an advertisement for a manager of a photo. establishment in a provincial town, which brought an answer asking my terms, &c., and stating that a person was required to manage, to operate well (both in gallery and field), first-class retoucher, good colourist and stippler (how many such do you know?). I replied that I could operate well, could use a pencil to retouch a negative to some extent, and could tint, but did not profess to be a colourist in the art sense of the term; that I would commence with four guineas per week (the pay of a first-class carpenter) until the business was proved and expenses up. My specimens were returned, with the intimation that the advertisers were in treaty with another party on more favourable terms.

"One of my sorrows—and, perhaps, not the least—is the loss of my weekly pleasure of perusing the News. I have not seen its familiar type since the one dated the 29th of September. I think I must ask you to have it posted weekly for a twelvemonth.

"I must now conclude by hoping that you have been in the enjoyment of good health, and, as old associations are, on my part, treasured and unforgotten, remain, yours very faithfully,
J. G. STRANDBERG."

DISTORTION FROM EXPANSION AND CONTRACTION OF PAPER.

We have more than once recently called attention to the distortion in portraits caused by the unequal expansion and contraction in albumenized paper in the various wettings and dryings occurring in printing operations. Dr. Vogel, in his letter to the *Philadelphia Photographer*, gives some interesting experiences of Berlin portraitists. He says:—

"The distortion is different in the length of the sheet rather than in the width of the same; for this reason the picture, the negative of which is put on in one or the other direction while copying, seems to be considerably stretched in the length or in its width. I have seen pictures copied on albumen paper of the same sheet, under the same negative, on the same day, toned, fixed, and washed in the same manner, on some of which the face of the person was lean, and on others thick and puffed up. About this circumstance there was at one time much said, and many photographers, although the pictures showed the fault, denied the fact entirely. Especially those photographers who were working for builders and engineers could not be convinced, because they did not like to admit that their pictures were useless. It is evident that, if this distortion appears always, the proportions of measurement in drawings, &c., must become entirely different, and then, of course, the picture is not correct. One of these photographers, Mr. Marowsky, has investigated the matter carefully, and shown that the distortion on his pictures is, indeed, a very trifling one, or entirely unnoticed, even if he uses strongly albumenized paper. Thereby it is discovered under which circumstances the distortion especially appears. Mr. Lindner, who noticed the distortion on his cards in a very remarkable manner, was accustomed to trim his pictures immediately after copying, and then, as usual, he toned, fixed, and washed the same, and at once, after coming out of the washwater, he pasted them, and put them on Bristol board. In this case the distortion was a remarkable one. But if we allow the picture to dry after being washed, and paste it up, no distortion is to be noticed. The fact is that the dry picture during the short time of moistening with paste has no time to expand to any great degree. An expansion takes place, but at first in equal directions, which is harmless; for that reason we notice no distortion on pictures treated in that manner. But if the pictures remain very long in the water, the expansion in the width of the sheet from which they are cut is considerably greater than in its length; and when they are pasted up, this unequal expansion will remain after drying. The expansion is so remarkable that even the people notice it by comparing two pictures. Though the whole matter is a fault, under certain circumstances it is an advantage. Very often we find persons of excessive meagreness, who wish to appear in their pictures a little stouter, or stout persons who like to appear in their pictures more slender. By the above fault it is in our power to gratify their wishes."

ON THE DEPTH OF PRINTS AND INTENSITY OF NEGATIVES.

BY CAPTAIN ARNET, R.E., F.R.S.*

[In my last communication it must have been seen that there is a slight error in the diagram. At the extremities of the horizontal line the figures 0 and 1 should have been placed, and .25, .5, .75 should have divided this line into equal parts. The top figure of the vertical axis should have been 1, and not .1 as shown.]

Enquiries having been made as to the mode of obtaining a monochromatic light, I have thought it better to treat of this in my present article, before going further into the opacity of negatives and depths of prints. The most common monochromatic light, undoubtedly, is that caused by the introduction of sodium into a colourless flame. The

most usual way of obtaining this light is by taking a piece of platinum wire, and bending the end into a small loop about one-eighth of an inch diameter. By slightly moistening the loop a particle of common salt (sodium chloride) can be easily taken up by it. The loop holding the salt is next placed in the flame from a Bunsen burner or a spirit lamp, when the salt melts and forms a small transparent bead. Whilst still hot the loop is brought in contact with more salt. Another small crystal will adhere, and this should be melted into the first bead. This operation is continued till the loop is entirely filled. Sodium carbonate may be substituted for the chloride, and some people seem to find this easier to manipulate. The latter should be well dried before an attempt is made to form the bead, otherwise the attached moisture causes the crystals to fly off the loop when they are introduced into the flame. A couple of beads thus prepared will suffice to give a fair light if placed in the outer portion of a Bunsen or spirit lamp flame. The wires, for convenience sake, should be attached to stands, and should be placed as not to interfere with the light issuing in the direction in which the drum or any other object is to be illuminated. Where a larger volume of coloured flame is required, a bunch of asbestos soaked in a strong solution of brine may take the place of the bead; it will be found that this method has a slight tendency to cause a flickering, which is decidedly objectionable. It has been suggested to dissolve common salt in the spirit of a spirit lamp, in order to give an illuminating flame; this gives a feeble light, and the salt is apt to cake about the wick.

There is another method of obtaining the sodium light, which is, indeed, applicable to the light obtainable from any other easily volatilized metal. If a very fine spray diffuser be caused to play in the flame of the Bunsen burner a large volume of coloured flame results. For spectroscopic work this is invaluable. For convenience sake it is better to use some contrivance for keeping up the small current of air that may be required. One simple plan of effecting this is the foot blower manufactured by Fletcher, of Warring-

Fig. 3.

ton; another also suggests itself. Procure two large bottles with widish mouths, and fit each tightly with a cork; pass two pieces of glass tubing through the corks, one just penetrating the other almost reaching to the bottom of the bottle. Now nearly fill one bottle, A, with water, and replace the cork with glass tube attached. Invert the bottle; the longer piece of tube should be above the level of the water, the other end being open to the air, whilst the other tube should be closed to prevent the water flowing out. A piece of india-rubber tubing should be drawn over the end of this short tube, on which should be placed a pinch-cock, such as used by chemists, to prevent the flow of water, though an American clip will answer the purpose. The other bottle, B, is now inverted empty, and a piece of india-rubber tubing connects the long glass tube with the spray diffuser, whilst the short tube is attached to the india-rubber tube which has been closed by the pinch-cock, and which is attached to the short tube of A. The two inverted

bottles are placed in stands, A being placed higher than B. The water in A rushes out as fast as the air is displaced out of B, through the spray diffuser. A continuous current of air is thus kept up for some time, and the operation can be repeated by detaching the tube from the spray diffuser, and reversing the positions of A and B. Either a watery or an alcoholic solution of the salt to be used may be placed in the diffuser, as experiment may prove best. By this means a flame coloured by lithium, strontium, calcium, &c., may be produced.

When the examination is to be conducted by red light, however, it may often suffice to use flashed ruby glass placed in front of a paraffin lamp, which usually burns with a very steady flame.

To get almost absolute purity of colour, it is as well to use the spectrum; but unless the oxyhydrogen or electric light is at the command of the operator, this method is not admissible for working at night. Of course sunlight is *par excellence* the best, and it is from this source, from which the spectrum can be produced that will be described. A darkened box, A A, should be prepared (to place on the operating table, fig. 4), a convenient height for which

Fig. 4.

is about two feet six inches: one side should be open, but capable of being covered with a cloth to exclude all extraneous light. In the centre of the top of the box should be a mirror, B, six inches by twelve inches, placed in a plane of 45° with the top, and at right angles of the plane of the unclosed side of the box. Any light reflected from the mirror must be admitted to the interior of this box on to the table (or object D, placed on it) through a slit, C, of about half an inch wide and seven or eight inches long, at right angles to the mirror. This arrangement for obtaining the spectrum is shown in the accompanying diagram.

Fig. 5.

A is a glass jar of a cylindrical shape, filled with water, placed before a fairly wide slit three or four inches high. Into A is reflected by a looking-glass (not shown in the figure) sunlight. The distance of A from B is so adjusted that the slice of light refracted from it falls in the slit in B, so as just to fill it. C is a rough lens of about eighteen inches

focus, and capable of taking in all the light from the slit. It is placed so that the rays *slightly* diverge and fall upon two prisms, of which a fuller description will be given presently. These refract the rays till they fall upon E, another rough, convex lens of about four or five inches diameter and three feet focal length. The rays are received upon the mirror, B, attached to the box-lid in which the spectrum should be thrown fairly in focus. The box is now adjusted till any particular ray of light falls through the slit H on to the object D in the box. The width of the spectrum is enlarged by moving the lens C till it well covers the length of the slit. It will be seen at once that any monochromatic light may be employed by this artifice, and the illumination will be sufficient by which to obtain readings. (It should here be remarked that the rotation of the drum may be caused by attaching the large wheel to a fly-wheel and treadle. I have myself attached it to the table of a sewing machine.) Prisms of the size required, if made of glass, would be expensive. They may

Fig. 6.

readily be formed out of Winchester quart bottles, cutting them at the desired angle. If a piece of paper be fitted round the bottles, and they be immersed at the angle required, the water will give lines in the paper, from which a pattern may be cut to guide the cutting. When so marked, a small part of the line marked on the bottle should be filed, and the cutting finished by means of a pastile. The edges should then be ground on a flat stone, and two flat pieces of glass cemented on to the wedge, thus formed by means of a solution of glue and treacle to which a little glycerine has been added. A hole should be drilled at the top of the prism to enable carbon disulphide to be inserted.

In reading strips of darkened paper, it is sometimes difficult to ensure accuracy if the paper be glazed, owing to reflections from its surface. This evil can be nearly eliminated by causing the illumination to come through finely ground glass. In any case it is as well not to trust to observations taken by one person: at least two should take readings to prevent a chance of error, and they should be taken first moving the tint to be compared from the black end of the cylinder to the white end, and then *vice versa*. Personally, I prefer to read with one eye closed and accurately focussed on the junction of the tint with the rotating surface. I also find it necessary to have a uniform shade pasted on each side of the rider holding the scale, as, if one side be white and the other black, there is a decided tendency to get variable readings. My experience teaches me that the eye must be thoroughly trained before great reliance can be placed on any person's readings. Ladies—who are, perhaps, more accustomed to match colours—seem to judge more correctly at a first trial than do my sex. More than thirty readings without resting should never be attempted, as the fatigue to the eyes is very great.

ON THE IMMEDIATE AND POSSIBLE EFFECTS OF CERTAIN RECENTLY-PROPOSED ADDITIONS TO THE NEGATIVE BATH.

BY W. HOWARD.

"CARBON *shall* be king!" "Silver is our sovereign!" These are the battle cries that alternately stun and invigorate the contending factions of the photo-printing world. Fortunately, however, for the preservation of good-feeling, neutral—or, rather, mutually important—matters frequently claims their attention. I allude to the negative bath, without due attention to which, neither school of printers could be put into possession of negatives capable of pro-

ducing satisfactory proofs. True indeed it is that even that time-honoured "institution" may soon be dispensed with ("a consummation devoutly to be wished") but, while for all but special purposes it still remains the corner stone of the "black art," aught that may be written concerning it can scarcely be deemed "flat, stale, and unprofitable." This, at least, was my personal feeling, and, fortified by a hint from our energetic Editor, I have ventured to put into a readable garb a few stray observations affecting it.

Having, however, in my mind's eye the somewhat lame and impotent results arrived at by a "learned, grave, and reverend" body in a recent though long-prolonged discussion, I have carefully avoided any endeavour to flood with new light the subject of pinhole production. On the contrary, I have chiefly directed my attention to agents which are recommended for their removal, or to collateral matters. In the annals of photography, the year 1865 was, if my memory holds good, remarkable for the amount of attention devoted by experimentalists to the subject of pinhole production, and it was then fully demonstrated that the formation of nitro-iodide of silver in the bath, and its subsequent precipitation upon the plate, was the main cause of these pests. If to this we add the more recent discovery of the frequent production of sulphate of silver in the bath, we have about exhausted the catalogue of well-defined but unavoidable pinhole propagators. If any operator is careless enough to court danger by avoiding the minor trouble entailed by filtration, he scarcely deserves the mildest manifestation of sympathy on his behalf. I have just, perhaps, incautiously used the term "unavoidable," in speaking of the recognized enemies; at least one of them may be circumvented by Mr. Eliot's method of working—but of that more shortly.

Amongst the host of suggestions for improving the working qualities of our negative baths, or removing some of the many disorders to which they are liable, Mr. D. G. Munger's unpremeditated experiment with a piece of soda hyposulphite is worthy of attention, on account of the discrepancy which exists between the results obtained by him and those which the popular imagination had conceived would follow such an unorthodox proceeding. Mr. Munger's own words very well indicate the nature of this conception. He says:—"Judge of my surprise when, upon developing, not a hopeless fog, as I had expected, but an unusually clear chemical effect was presented." To put this sentence into other words, the addition of a small quantity of hypo reduces or prevents fogging. The first enquiry which I set to work to resolve was, naturally enough, "Does hypo possess this power?" The second, "What is the nature of the reaction which ensues upon its addition to the bath?" and the third, "Cannot the same end be achieved by less suspicious means?" I commenced operations with a newly-prepared neutral bath, which, if made with good nitrate, is the condition that, next to one rendered alkaline by silver carbonate, my experience, which is not professional, leads me to prefer. A few trial negatives were taken with this bath. The light was yellowish, being that of an evening sky, and exposures varying from five to eight seconds produced no fog; ten seconds were required for that purpose. The subject was the somewhat inartistic array of roofs, chimney-pots, and garret windows mixed with a liberal hand, and taken from the vantage-coign of a two-pair back. For the purpose in view this was, however, a sufficiently crucial test. The next step was to make the good bath into a foggy one; that was a thing easily accomplished by putting into it some silver oxide at the close of the evening, and permitting it to digest that until again brought into requisition.

Here I may remark that, as far as I can judge, nothing has more conduced to the general feeling of distrust with which alkaline or neutral baths are regarded than the fact that their alkalinity—or, as by a little carelessness on the part of the operator, it may have been called neutrality—

I must in fairness to Mr. Munger admit that at present I have not found these defects to occur; this I think solely arises from the fact that the experimental solution was used immediately after filtering off the sulphide precipitated by the hypo, and could consequently contain only the very slight trace of sulphate of silver derived from the oxide of that metal dissolved therein.

If any bath has accidentally been treated to a dose of "hypo," I would advise the addition of nitrate of baryta to get rid of the sulphuric acid. If a newly made bath does fog the plates, it can easily be rendered acid by the usual method (i.e., nitric acid), avoiding any loss of silver, and liberating no compound fraught with the possibility of future evil, as this process does.

(To be continued.)

Correspondence.

ADULTERATIONS OF NITRATE OF SILVER.

SIR,—I have been frequently asked by photographers how to detect adulteration in nitrate of silver, and it may prove of some interest to your readers to know that the adulterant is principally in the dust. Out of about twenty samples that have been sent to me for analysis, four were adulterated. The adulterant, which is usually nitrate of potash (saltpetre), is introduced in a powdered state, as there is no other way of safely mixing it, for it crystallizes in long needles, whereas nitrate of silver crystallizes in slabs. Owing to this, large crystals would soon betray the fraud; and the two salts will not crystallize together. This hint may be of some use to consumers. Of course unprincipled dealers have a ready answer to any objection made to the dust: either it is the bottom of the jar, or the nitrate has been shaken whilst travelling, or such like. A perfect sample of nitrate of silver must be free from any yellow tinge, perfectly white, and have a glassy appearance; the crystals must be large, and there must be no powdered substance mixed with it.

I hope you will kindly insert these few lines in your paper for the benefit of those concerned in photography.—I am, sir, your obedient servant, ALFRED LUTCHMAIN.

Proceedings of Societies.

AMATEUR PHOTOGRAPHIC ASSOCIATION.

A COUNCIL meeting of this Association was held the 4th inst., SIR ANTONIO BRADY in the chair.

The minutes of the last meeting having been read and confirmed, the SECRETARY read letters from Lord de Ros and Dr. Arthur Farre, expressing their regret at being unable to be present.

The following members and subscribers were elected:—Sir George Prescott; H. Davies, Esq.; Ernest Soutter, Esq.; J. W. Young, Esq.; R. Leventhorpe, Esq.; E. Swinburne, Esq.; A. Watkins, Esq.; Mrs. Herbert Evans.

The SECRETARY laid before the Council the pictures for the current year, and Mr. Glaisher, before reading his annual report, remarked that he and his brother referees, after carefully examining every picture, were much gratified to find that the negatives sent this season by the members were certainly better than those of any previous year. The works of Dr. Cooke, to whom was awarded the first prize last year, were even better than ever, and some magnificent pictures by Mr. R. O. Milne were deserving of especial attention; in fact, Mr. Glaisher thought that nearly every contributor gave evidence of improvement, and he considered that this sign of not merely sustained, but increased, vitality in the Society must be most gratifying to the Council, especially at this period of unusual depression.

The following is an abstract of Mr. Glaisher's report:—

Class 1 contains 90 pictures, contributed as follows:—Dr. Cooke, 17 large pictures; R. O. Milne, Esq., 13 large pictures; F. Beasley, Esq., 18; W. S. Hobson, Esq., 7. Major Chadwick, 7 large pictures; J. McAndrew, Esq., 5 Spanish scenes; R. Murray, Esq., 5 dry plate pictures; J. C. Stanning, Esq., 3; J. Adams, Esq., 3; W. Vanner, Esq., 3; T. Brownrigg, Esq., 2;

F. Schwabe, Esq., 2; F. Adderley, Esq., 2; Lieut. S. G. Fairtlough, 2; Capt. D. McNeill, 1.

Class 2 comprises 90 pictures contributed as follows:—R. Murray, Esq., 6; J. McAndrew, Esq., 6; Dr. Cooke, 6; Capt. D. McNeill, 6; F. Beasley, Esq., 5; F. Adderley, Esq., 5; P. Gunion, Esq., 5; W. Vanner, Esq., 5; W. H. Kirkby, Esq., 5; W. S. Hobson, Esq., 4; J. C. Stanning, Esq., 4; R. O. Milne, Esq., 4; Lieut. S. G. Fairtlough, 4; Capt. J. B. Fox, 3; Major Chadwick, 3; A. L. Stevenson, Esq., 3; G. W. Keeling, Esq., 2; T. Brownrigg, Esq., 2; S. G. B. Wollaston, Esq., 2; J. Adams, Esq., 2; F. Schwabe, Esq., 1; K. D. Roberts, Esq., 1; W. W. Unett, Esq., 1; Miss L. Cox, 1; W. Muller, Esq., 1; Mrs. Deeble, 1; Rev. H. Palmer, 1.

Class 3 comprises pictures contributed as follows:—F. Adderley, Esq., 10; S. G. B. Wollaston, Esq., 7; Mrs. Deeble, 9; Capt. D. McNeill, 7; J. McAndrew, Esq., 7; K. D. Roberts, Esq., 6; P. Gunion, Esq., 6; H. V. D. Esterre, Esq., 6; A. R. Hunt, Esq., 5; W. Vanner, Esq., 4; W. Muller, Esq., 4; Rev. H. Palmer, 4; Miss L. Cox, 3; A. L. Stevenson, Esq., 2. Lieut. S. G. Fairtlough, 2; J. Adams, Esq., 2; Capt. J. B. Fox, 2; E. Milne, Esq., 2; G. W. Keeling, Esq., 1; F. Beasley, Esq., 1; F. Schwabe, Esq., 1; G. M. Green, Esq., 1; J. C. Stanning, Esq., 1; R. O. Milne, Esq., 1; W. H. Kirkby, Esq., 1; W. W. Unett, Esq., 1.

The remainder of the pictures are arranged in Classes 4, 5, and 6.

The following prizes were awarded:—

Dr. Cooke, first prize, for Nos. 53, 57, and 62, a large Silver Goblet. R. O. Milne, Esq., second prize, for Nos. 53 and 62, a Silver Goblet. Major Chadwick, for Nos. 4 and 8, an Oil Painting in frame. F. Beasley, Esq., for Nos. 273 and 274, a large Album elegantly bound in morocco. W. S. Hobson, Esq., for Nos. 145 and 146, a ditto ditto. J. C. Stanning, Esq., for Nos. 38 and 39, an Oil Painting in frame. F. Adderley, Esq., for Nos. 13 and 14, a ditto ditto. R. Murray, Esq., for Nos. 118 and 121, a ditto ditto. W. Vanner, Esq., for Nos. 5 and 12, an Album, elegantly bound in morocco. T. Brownrigg, Esq., for Nos. 33 and 34, a ditto ditto. Lieutenant S. G. Fairtlough, for Nos. 5 and 8, an Oil Painting in frame. Dr. Cooke, for Nos. 56, 58, and 66, a ditto ditto. R. O. Milne, Esq., for Nos. 60 and 61, an Album, elegantly bound in morocco.

Certificates of Honorable Mention were awarded to Captain D. McNeill, J. Adams, Esq., F. Schwabe, Esq., and J. McAndrew, Esq.

A vote of thanks was proposed by the Chairman and seconded by Mr. Gooch, to Mr. Glaisher, for his able report; and a vote of thanks was proposed by Mr. Gooch and seconded by Mr. Howard to the referees, for the time and trouble they had bestowed in the examination, arrangement, and classification of the pictures. Both votes were carried unanimously. A. J. MALVERN, Hon. Sec.

Talk in the Studio.

THE LAW OF LIBEL.—Referring to some recent remarks in our columns on the possible interference of the law of libel in case of publishing adverse and injurious comments on commercial products, Mr. W. T. Bovey courteously writes to point out what he conceives to be an error in our view of the case. We expressed a conviction that a journal publishing a fair and honest report of proceedings which were libellous in themselves would be exempt from action. Mr. Bovey thinks this is a view of the law as it ought to be, but not as it is. A friend of his was recently mulcted to the tune of £250 for publishing a verbatim report of the proceedings at a meeting of a Sanitary Board, in which enquiry was made into the character and conduct of a parish official. On the other hand, Captain Burton is satisfied that any such libel would be successfully defended by pleading justification. Such a plea is well known to be one of the most dangerous to plead, and one of the most difficult to sustain. We have no intention, however, of experimenting in this direction.

NO INK REQUIRED.—We have been favoured by Messrs. Mawson and Swan with some examples of the "Miraculous Pen," for which they are agents. The pen well merits its name, writing admirably without the need of ink. The pen is simply dipped into water, and is found to be at once charged with ink, black or blue, or violet or red, and writes freely. Nothing can be more handy and convenient, as we have already proved. The pen does not oxidize, is always clean and ready for use, and is suited to ordinary holders. A sample book of fashionable repp papers of different colours suggests that this firm is supplying stationery of excellent quality.

AN ARTIST'S SKETCH-BOOK.—We are favoured by Mr. J. Greer, of Pendleton, with an example of the utility of photo-

graphy in the literal reproduction of an artist's sketches. A volume of "Scrapes from an Artist's Sketch-Book," by Mr. Helmut Rothwell, contains photographic reproductions by Mr. Grear of the author's sketches in Rome and elsewhere, often made in positions where photography would have scarcely been available for producing the original scene. The pictures are often fine, the descriptions are graphic and interesting, and the photography very good.

"DESIGN AND WORK."—We are favoured by the publisher with the second volume of "Design and Work," a technical journal of great excellence. For the amateur, or practical man, whose hobby or duty brings in contact with mechanics, electricity, chemistry, machine work of various kinds, such a periodical must be very valuable; and as photographers are generally ingenious, and amateurs in various art industries, "Design and Work" will interest and help them.

SCREENS FOR REMBRANDTS.—A correspondent says:—"The slide screen I use is one described in the Year-Book of Photography, but I have covered it with blue calico, the dead side of the calico being outside. I can gladly state that I get extremely fine and soft shades with the screen, and should greatly advise other photographers to use the same, as it cuts off a tremendous lot of exposure which would otherwise be required in photographing Rembrandt heads, the screen doing away with a great amount of other screening which would otherwise increase the exposure."

BASHI-BAZOUKS AMONGST THE CHEMICALS.—The Special Correspondent of the *Newcastle Chronicle* with the Turkish army writes:—"An incident which recently occurred has caused a good deal of amusement among the inhabitants. A party of Bashi-Bazouks visited the store of Mr. Donnes, a photographer, during that gentleman's absence, and helped themselves freely to everything there was in the place. In the studio they found something which they took to be sugar, and ate freely of it. Eight of them died. Mr. Donnes was sent for by the Civil Governor, and at once admitted that he kept poison on his premises. He was then informed of what had occurred. The Governor did not even reprimand him, he probably not being particularly sorry that these troublesome fellows had been disposed of in such a way."

BLISTERS ON ALBUMEN PAPER.—The *Photographische Mittheilungen* gives the following as a very effective remedy against blisters on albumen paper:—"Use an alcohol bath, in which the pictures are allowed to remain, after the gold bath, until they have a glassy appearance; the time required is from two to three minutes. They are then dipped into water, and treated in the usual manner. This alcohol bath can be used about twelve to fourteen days, and may be used in lamps for lamp purposes, thus the cost is reduced materially."

TO REMOVE IRON SPOTS FROM MATERIALS.—This question was answered as follows by Mr. Grune, in the session of the Society for the Promotion of Photography. The spots are coloured blue with yellow prussiate of potash; wash with caustic soda, treat it with oxalic acid, afterwards washing well with water. Treated directly with oxalic acid, only fresh spots disappear.

To Correspondents.

C. S. HERRICK.—The grievance you describe seems to be really a monstrous one, if there be no unconscious error in the matter. There should be a remedy for such a wrong; but we must confess that we do not see at present in what it consists. Our correspondent's grievance should be stated as a caution to photographers generally. He sent to a presumably respectable firm, advertising in our pages, six pounds of antonised silvered paper cuttings, four pounds of chloride of silver, and four ounces of residues of gold toning bath, and received as the value of the whole the sum of fifteen shillings! The amount of silver in sensitive paper we cannot precisely estimate; but in four ounces of chloride of silver there should be three ounces of pure silver. If, instead of sending residues for unconditional sale in this way, the refuser were asked to make an assay, and from that state the worth of the whole, the same risk of disappointment would not arise. We are very sorry when any announcements in our advertising pages mislead readers; but, as we have before had occasion to remark, we accept no responsibility whatever for the statements or acts of advertisers. We could not, if we were anxious to do so, verify the statements or bona fides of advertisers: beyond their commercial dealings with ourselves, we, as a rule, know nothing of their commercial dealings or status, and bear no responsibility of any kind in relation to them.

FORST.—The use of a wash in a weak solution of alum has been proposed in America as an aid to permanency. We do not see the least reason to hope that permanency will be secured by such treatment, nor is there any evidence to show that such a result follows the use of alum. 2. The stains on the film are due to the use of a collodion in giving a horny repellent film, upon which the silver solution collects in drops, pools, and streams, instead of flowing off in an even wave. The silver solution so standing upon the plate generally makes stains of matt silver like slug tracks or oyster shells, and sometimes transparent markings, caused by the silver solution standing becoming concentrated by evaporation, and then dissolving the iodide of silver from the film on the spot where the accumulated silver solution rests. The best remedy is to use a ripper collodion, if possible, add a portion of a ripper collodion to that you are using. If you cannot do this, try adding a drop or two of distilled water to each ounce of the collodion, and shake well. Do not remove the plate from the bath until the solution flows over it without any tendency to separate into greasy-looking lines and streams. Move the plate well up and down whilst in the bath. Place wet blotting-paper at the back of the plate in the dark slide. The defect is not in the silver bath. 3. We see no reason to suppose that the use of heat in rolling or burnishing will injuriously affect permanency. It is, unfortunately, a general experience that the silver prints of the present day are not so permanent as those produced a dozen years ago; but whether this is due to less care in production, or to the inferiority of some of the materials used, it is difficult to decide.

A. BROWLAK SCHRIBER.—Tracing-hnen which is very transparent will probably answer best for covering such a screen as you desire. We are glad you find the blue screen answer. Robinson's "Pictorial Effect in Photography" is, unfortunately, out of print. We are glad you found the developer answer.

AN AMATEUR SCHRIBER (Calais).—Mr. Newton, of whose emulsion you speak, resides in New York, in the United States. If any one in this country supplies his emulsion, it will be Mr. Atkinson, of Liverpool, of whom you may enquire for it. The notices of this emulsion have been in articles reprinted from American contemporary journals. Thanks for information regarding the Apparatus Hermajis.

VINCANT.—"Pictorial Effect in Photography," by Mr. H. P. Robinson, is out of print. Should it be reprinted, it will be duly announced.

W. O. BARRY.—You will find one or two recipes in the present number which will meet your wants.

F. P. (Hensley-on-Thames).—Your letter ordering copies of the PHOTOGRAPHIC NEWS should have been addressed to the Publisher, not to the Editor, who has no duty in connection with the sale of the paper. The error in this matter caused delay in transmitting you a copy, which, however, you have before this received.

NOODLE.—We suspect that your toning bath, if (as you say it is) strong in gold, has been touched with soiled fingers, or something which has decomposed it, and rendered it inert. Touching with fingers contaminated with hypo. would do this. The toning process that went on in the hypo. was probably sulphur toning. Probably the gold solution was a little acid, and the prints saturated with it would cause sulphur toning at once on being placed in the hypo.

TRUO.—The yellow stains on the prints you enclose are undoubtedly due to imperfect fixation. As it occurs in patches, it is probable that the prints have been stuck together in the hypo, and so prevented the perfect action of the solution over all portions of the print, or the formation of air-bubbles on the print whilst in the hypo would cause a similar result. Prints should be kept moving and constantly separated whilst in the fixing bath.

H. J. M.—The office for registering photographs is in Stationers' Hall, Paternoster Row. A fee of one shilling is charged for registering each picture, and the cost of a form on which the proper details are to be written is one penny. Personal attendance is necessary. If you are not able to attend yourself, our publisher will undertake the duty for you. Send a copy of each of the prints to him, with title, &c., and 1s. 6d. in stamps for each picture, and he will attend to the matter.

B. B. S.—Received. Thanks.

CAPTAIN WATSONHOUSE.—Thanks for interesting letter. The back numbers shall be forwarded.

G. H. T.—Unless you are familiar with processes of printing by development, you will find it better to make an enlarged negative and print from that. If you prefer to enlarge direct on paper, take special care to avoid any trace of light reaching the sensitive paper or unfinished print, and use an aceto-nitrate bath. A few grains of common salt in the developer will often keep the paper white.

A. SCHRIBER.—The spots on your card have the appearance of those produced by so-called gold printing; the particles from which produce similar spots or prints. The name and address of your card is scratched was; whether it was printed with bronze or not we cannot tell. If not, perhaps the print has been amongst other cards so printed.

Several Correspondents in our next.

The Photographic News, August 3, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

PHOTOGRAPHIC RECORDS OF POLITICS—THE IMPORTANCE OF CONTACT IN CARBON PRINTING—THE SUNSHINE RECORDS AT THE ROYAL OBSERVATORY.

Photographic Records of Politics.—It is possible to record a great many things by means of photography, whether they be the fluctuations of light and darkness in this world of ours, the magnetic pulsations of the earth, or the temperature and pressure of the atmosphere. But we think it will be news to our readers to find that changes in the political horizon may be prognosticated by the same means. In France, just now, as everybody knows, there is a good deal of speculation as to the ultimate result of the voting which is to take place in the autumn, and the political barometer is watched every day with considerable interest. In the meantime facts reach us to show how energetically the under-currents are moving. One photographic firm alone in this capital is executing an order for no less than thirty thousand Prince Imperials, which will, we suppose, be circulated throughout the country in the interest of Imperialists; while Republicans, on the other hand, are distributing pictures in abundance in the cause of MM. Thiers and Gambetta. The latter party do not confine themselves to photography, and an order has been received by one of the London comic papers for an almost unlimited supply of one of the cartoons recently published, which had a Republican tendency. No doubt, if we were to enquire nearer home, we should be able to deduce a very sound result as to the popularity of this or that political leader by the demand for his portrait among photographic dealers. Earl Beaconsfield, especially after the vindication of the Stationery Office appointment, would probably be in considerable demand just now, while after the atrocities of the Russians in Bulgaria we should possibly find a falling off in the demand for pictures of those statesmen who have lately been espousing the cause of the Muscovite. Many may think it a matter of little moment whether a shopkeeper sell a dozen or so of one portrait more than another, but when we hear of a supply of thirty thousand pictures being made by one firm alone, it is not so insignificant, after all, whether regarded from the producer's point of view, or the influence which such pictures have upon public opinion. There cannot be a doubt, for instance, that if one morning all London woke up to find the portrait of a certain individual staring at them from the windows of every photographic dealer, that individual would have become famous before night had fallen. Many persons, both of high and low degree, have had their popularity infinitely increased—nay, altogether created—in this way; and one of these days we shall have photographic publishers besieged by individuals thirsting for publicity in the same way as editors of influential newspapers are. *En revanche*, we know many a photographer owes a good deal of his income to such publications, and we could name three or four, forsooth, who have made a nice little fortune out of the portraits of one individual or another. If only statistics could be collected of the number of copies of different portraits sold every year, how interesting they would be to read!

The Importance of Contact in Carbon Printing.—There is one point in connection with carbon printing which deserves attention, especially at this season of the year, when the tissue is apt to get stiff, if not horny and brittle, by lack of moisture. It is this: that without very particular care on the part of the printer, there will be want of contact with the negative and tissue. Ordinary pressure, such as will serve to maintain a piece of limp albumenized paper in close contact with the cliché, is of no

avail when printing small pictures in carbon. Unless there is absolute contact all over the surface in such cases, it is next to impossible to get a sharp picture. In winter it may be done, for then there is plenty of moisture in the pigmented gelatine, and it presses flat without difficulty; but with a thick and horny substance, as the tissue is frequently in summer, far more pressure than usual is absolutely necessary. The tissue may have a glazed surface imparted to it from being partially dried upon a patent plate after sensitizing, and this helps matters a good deal; but even in this case, when small and delicate cartes-de-visite are to be printed, considerable care must be taken. Another point, perhaps hardly less important in connection with carbon printing in bright summer weather, is the screening of the fresh tissue from light. It was customary during the early days of carbon printing to have quite a contempt for diffused light, and the work was carried on in a well-lighted room, the tissue, both exposed and unexposed, being contained in table-drawers in the same room. Such a *modus operandi* is, no doubt, all very well in winter and in cool, dull weather, but in the summer time, when a chance ray of light does twenty times more mischief than at other seasons of the year, and when the dry air around robs the tissue of every available particle of moisture, matters are different altogether, and it behoves the printer to be far more careful of his materials. It is impossible to secure pure whites under such circumstances, and, moreover, reticulation in the tissue will not be long in showing itself, if better care is not taken to prevent it from the hot, dry air.

The Sunshine Records at the Royal Observatory.—It has been the custom now for some months past to observe the weekly duration of actual sunshine at the Royal Observatory at Greenwich, and last week it was reported that out of 112 hours during which the sun was above the horizon, it only shone for 37·8 hours at Greenwich. A dull week, certainly, for photographers, it would appear, and yet such was far from being the case, for the fact is that in this summer weather bright sunshine is rather in the way than otherwise. Unless it is a question of black and white printing, photographers do not care to expose their negatives in the sun, and for most purposes the sun behind a thin veil of cloud is to be preferred by photographers to the blazing sunshine itself. In truth, not only for photographic purposes, but for most other things, it would be far more to the purpose, we cannot help thinking, if the authorities at Greenwich, instead of telling us the total number of hours during which the sun appeared from behind the clouds, were to inform us of the total amount of light shed upon the earth during the week. Many would have a difficulty in saying what is sunshine and what is not; whether the time during which the sun appears bright and bare in the heavens only should be counted, or whether the whole period should be timed during which shadows are cast by the solar orb. There should be no difficulty, with the scientific appliances now at our disposal, to record the actual intensity of the light from time to time, and in this way a total might be arrived at showing the value of the rays (in degrees) that have reached the earth within a certain period. Were this mode of record adopted, there would be no difference of opinion as to what is sunshine and what is not, and for the sake of the uninitiated a statement might be made that the number of degrees of light registered during a week is equivalent to so many hours of pure noon sunshine—say on Midsummer's Day. A light register of this kind would be of considerable value, not only to the photographer, but to the farmer, the agriculturist, the mariner, and others who make some study of the rainfall and other meteorological records. Indeed we do not see why the Royal Observatory at Greenwich should not supply us with both kinds of record.

INVESTIGATION OF ARTIFICIAL COLOURING MATTERS.

SUITABLE AS ANTI-PHOTOGENIC AGENTS—A SUITABLE DARK-ROOM WINDOW FOR BROMIDE OF SILVER PREPARATION.

BY M. CHARLES BARDY.*

THE interesting emulsion process of M. A. Chardon requires that in the preparation of the material no light should be admitted having an action upon bromide of silver. I may, therefore, be able to render some service to those who occupy themselves with the process, by pointing out an easy method of replacing the yellow glass in their dark rooms, which permit a large quantity of the actinic rays to pass.

For the past two years I have made a study of bromide of silver in dry processes, and I employ, for the purpose of intercepting the light in my laboratory, sheets of glass tinted with colours derived from coal tar. Among the substances which I have tried, one possesses in a high degree the property of arresting active rays, and that is chrysoidine. Chrysoidine is a yellowish red colouring matter, and is made in England. It is a crystalline substance, soluble both in water and in alcohol. This property permits of its use in different ways; namely, as a varnish, in collodion, in a solution of gelatine, &c.

To make a varnish with chrysoidine, it is sufficient to dissolve it to the point of saturation in any alcoholic varnish, to permit the liquid to cool, and to filter it. The varnish is then employed in the ordinary way. By replacing in the preparation of collodion the alcohol, by a saturated alcoholic solution of chrysoidine, a very highly tinted collodion may be secured. As the ether, when the saturated solution is added, will precipitate some of the chrysoidine, it is well after mixing to allow the collodion to stand awhile, and then to decant it.

Either collodion or varnish prepared in this way and applied to glass will serve as a substitute for yellow glass, and is better than the latter in the preparation of bromide of silver. In some cases it is well to coat both sides of the glass with the liquid. One of the best ways of employing the chrysoidine is, to put it into pellicles of gelatine. The following formula will give some idea of the proportions to be employed:—

White gelatine...	20 grammes
Water	125 cub. cents.
Chrysoidine	2·5 grammes
Glycerine	3 cub. cents.
A two per cent. solution of alum	40	..	

You commence by dissolving the chrysoidine in the 125 cubic centimetres of water, warming the latter to facilitate solution; the liquid is then filtered and allowed to cool, and you proceed in the same way as when making gelatine pellicles by M. Jeanrenaud's method, namely, by pouring upon a glass plate. It is well to make the pellicles as thick as possible, and to do this the glass plate is rubbed with talc, and after it has been collodionized the margins all round are rubbed with soft wax, so as to form a border. In this way a sort of tray is formed, into which the gelatine is poured. A levelling stand is employed to rest the plate upon, and it remains in position until the gelatine has set. Afterwards the film of gelatine is covered with collodion containing castor oil. In this way a very supple pellicle is secured of a red ruby colour, which, if properly prepared, prevents the passage of all actinic rays.

An excellent anti-photogenic paper may be made by impregnating strong paper with a solution of:

Chrysoidine	3 grammes
Alcohol	100 cub. cents.
Water	50 ..

This paper does well to intercept light in laboratories, to envelop articles sensitive to light, prepared plates, dry emulsion, sensitive collodion, &c. It is preferable to all

papers of the kind met with in commerce, and it is likewise very cheap, for the alcohol may be replaced by methylated spirit, or suppressed altogether; in the latter case, it is only necessary to see that the solution is kept very warm when the paper is immersed in it.

Eosine, a magnificent colouring matter, is equally soluble in water and alcohol, and it may be employed in precisely the same way as chrysoidine. Its colouring capacity being inferior to the latter, however, it is necessary to take at least double the quantity of eosine when employing it for the purposes indicated for chrysoidine.

I was led to use these two substances after a series of experiments which I conducted to ascertain the absorption bands produced by various derivatives of coal tar when examined under the microscope, and I may here cite some experiments which demonstrate the role which the spectroscopy may play, in studying the actinic properties of colouring matters.

1. Fuchsine or aniline red. This substance, the oldest and most generally known, presents a most characteristic absorption band; it is situated in the green part of the spectrum. If the micrometer of the spectroscope is so regulated that the division 100 coincides with the yellow sodium ray, and if subsequently there is interposed between the luminous source and the slit a small transparent vessel filled with a dilute solution of fuchsine, there will be seen a soft band covering the whole of that portion between the divisions 110 and 125 of the micrometer. By adding more and more of the colouring matter to the solution, so as to deepen this considerably, the band of absorption becomes more pronounced, and broadens both right and left, covering even the yellow sodium line, and in the end only permits the orange and red rays to pass, as also a portion of the violet.

This substance cannot be without influence upon the sensitive preparation of silver; the fact that, when very concentrated, the solution permits some of the actinic rays to pass, proves this in fact. A pellicle of gelatine, strongly coloured with fuchsine, interposed between the light and a film of Chardon emulsion, and covered with a negative, serves to produce a positive image in fifteen seconds in diffused light.

2. Naphthaline rose possesses a band of absorption situated between the divisions 120 and 145; the deep colour of this product appears to intercept all rays with the exception of orange and red. Although the eye cannot perceive the violet rays, it is evident that the band on spreading cannot cover all the spectrum, and that a portion of the violet rays is not absorbed. Naphthaline red associated with gelatine gives under the circumstances previously described a positive image in sixty seconds.

3. Eosine presents similar characters; the band of absorption in this case is not quite so broad, and it is situated between the divisions 120 and 140. In default of other substances, these two products, employed in the form of very deep solutions, may be made to give satisfactory results.

4. Chrysoidine has this particular trait—that it has no visible absorption band. If there be interposed between the source of light and the slit of the spectroscope solutions more and more charged with colouring matter, there will be perceived a sort of screen, which, starting from the violet, approaches, little by little, towards division 85 of the micrometer. From this moment, no matter what the concentration of the solution may be, the screen advances no further; but the intensity of the red and orange rays still diminishes. This manner of behaving itself leads one to think *a priori* that chrysoidine must fulfil in the most perfect manner the role of an anti-photogenic agent, and experience has shown such to be the case. A plate prepared with the Chardon emulsion, placed five minutes behind a glass covered with gelatine tinted with chrysoidine, gives no trace whatever of an image with alkaline development.

* Read before the French Photographic Society.

Under the same conditions an ordinary yellow glass will yield a positive image with an exposure of twenty seconds. And yet this yellow glass, which gives an image thus with bromide of silver, I have used without detriment for the glazing of my dark room when working the wet process. In examining this yellow glass with a spectroscope, it will be found that it does not intercept any of the rays of the spectrum; it simply weakens them.

It has been stated in the *British Journal* that an anti-photogenic screen may be produced by covering a glass with a solution of gelatine, and when this is almost dry, treating the same with a concentrated solution of permanganate of potash. We have examined plates prepared in this way with the spectroscope, and while they have appeared exceedingly opaque, they nevertheless allow the whole of the spectrum to pass, more or less weakened; in a word, these permanganate of potash plates behave in the same way as the yellow glass of which I have just spoken. Photographers will, therefore, do well to be very circumspect how they make use of the process.

We do not wish to affirm that substances to which we have referred will secure the most perfect immunity; we only say that they are more than sufficient to protect bromide of silver emulsions, and they will allow the photographer to work without being troubled with fog.

Artificial colouring matters being easily attacked by light, no doubt many will have their suspicions as to the durability of some of these colours. We are in a position, however, to state that there is no need for any misgivings on the subject. For upwards of a year I have had the window of my dark room glazed with a sheet of glass covered with chrysoidine collodion. Now, this substance has preserved to this day its anti-photogenic power, and serves for a screen against the light when preparing the bromide of silver films, as well as when first placed in position. And yet I may mention that, during the whole twelvemonth that the window has been in use, it has had sunshine upon it for some hours every day.

WASHED EMULSION.

BY JOHN C. BROWNE.*

About a year ago I made a photographic trip through Pike County, Pennsylvania, and on my return prepared an account of the expedition. Upon that occasion I used wet plates only, but the labour of transporting my outfit was so severe that I determined not to use a wet apparatus again in such a rough locality, if it was possible to depend upon any dry process.

During the past winter my attention was called to a sample of washed emulsion, prepared by Mr. Lewis P. Young, of Philadelphia, which gave good results in quick exposures, but a longer time was sure to spoil the negative by solarization, unless the plate was backed. This fault was so annoying that I had almost given up the idea of my contemplated Pike County trip this year, when Mr. Young handed me a sample of stained washed emulsion which he modestly said would not trouble me with solarization even in very long exposures. I tried the article, and the result far exceeded my expectations. In a few weeks I became quite expert in the development, and made arrangements to test its capabilities upon ravine views.

After some delay, Mr. Young agreed to accompany me, and we started for the Delaware Water Gap, where we joined Mr. Graves, who carried a complete wet outfit. For two weeks we rambled over a portion of Pike and Monroe Counties, going to many localities not visited before, and to all the best known objects of interest. The relief from the labour of carrying the heavy load necessary for wet work was an agreeable experience. We had no difficulty in going anywhere unassisted, and enjoyed the trip from beginning to end, having a large number of good negatives to show as the result. My own judgment might be considered at fault

* *Philadelphia Photographer.*

if I were to express myself as I feel in regard to the quality of the negatives, but I will say that some of the most critical judges have examined the work and pronounced it excellent. The time of exposure varied from a few seconds on bright subjects to considerably over an hour on dark ravines. The development was under perfect control, and proceeded almost as rapidly as a wet plate. No solarisation or fogging was noticed. I have been asked if the result with stained emulsion compared favourably with the wet collodion process, and I have answered that almost all the negatives made in Pike County are nearly in quality to wet plates, and a few superior, owing to the great latitude in exposure.

For the future, in making extended excursions with the camera, I shall discard my wet traps, and substitute a dry outfit. Mr. Young has cause to feel well satisfied with his success upon this occasion, and in the opinion of the writer richly deserves the thanks of photographers for placing in their hands such a valuable article.

A NEW GOLD SALT FOR TONING.

BY DR. J. SCHNAUSS.

UNTIL now there have been used only the single and double chloric salts of gold for toning. During the past winter Mr. Neumayer, student of chemistry from Munich, visited my establishment, and undertook under my directions the preparation of a gold bromide and a gold bromide of calcium, for the purposes of experimenting with these salts and their uses in photography.

Thin leaves of gold are readily dissolved in bromine water and in bromine gas. But a more rational and less disagreeable mode of preparation is by the action of hydrobromic acid, nitric acid, and aqua-regia.

During the evaporation of the gold bromide, which has a dark appearance and smells strongly of bromine, great care is necessary, owing to the fact that the gold bromide vaporizes more easily than the chloride. Bromide of gold is difficult to crystallize. By the addition of an exact equivalent of bromide of calcium dissolved in water, and evaporated, small granite-red crystals of double salts are obtained. $\text{KBr} + \text{AuBr}_3 + 5\text{H}_2\text{O}$ can be with difficulty dissolved in water; but a thin solution is of a deep red colour, and effloresces in dry air.

I have tried these double salts, also the gold bromide, with several additions, as a toning bath. In its general effects on silver copies it is analogous to gold chloride combinations, except that in the same proportions it acts more energetically.

The addition of soda bicarbonate gives a blue-black tone, melted acetate of sodium a purple-coloured tone.

For a lasting gold bath, in form of a *sel encausse*, these salts are recommended.—*Archiv.*

HOW TO TRANSFORM A SIMPLE PHOTOGRAPH INTO A PRINTING BLOCK.

In the *Photographisches Archiv* appear the details of a simple method of securing an outline photograph in metal suitable for printing with type in the ordinary printing press. It is necessary to be somewhat of a draughtsman, no doubt, in order to be able to do the work well and rapidly, although nothing is said on this head, but hardly any one could, haphazard, undertake the matter.

Only a well-marked photograph with bold lines, and in which minor details are of no account, is suitable, and the negative is in the first place put into a camera or other apparatus to furnish an enlarged positive. Upon this enlarged positive are traced, in Indian ink, the bolder lines which it is desired to retain, a pen or brush being employed for the purpose, according to the nature of the work or the desire of the draughtsman. After all details have been in this way traced, with thoroughly black pigment, the lines of a thickness corresponding to the original

object, and of such a nature as to be readily reproduced by photography, the print is treated with chloride of lime or other bleaching agent, and in this was the whole of the image obliterated with the exception of the black lines made by the draughtsman.

The picture is now photographed, and in this way a small negative secured, or one, at any rate, of the dimensions of which the printing block is to be. In this case the negative will be perfectly opaque in the lights and transparent in the shadows, and from it may be easily produced by any of the etching processes an engraving upon zinc capable of being used in the printing press with type.

Chloride of lime is specially mentioned as the bleaching agent wherewith to render invisible the details of the silver image, after the draughtsman has done his work. We should think that a solution of bichloride of mercury would be much more effectual in making the original photographic image disappear.

ART CONSIDERATIONS IN POSING THE SITTER.

BY M. A. ROOT.*

PHOTOGRAPHY is justly entitled to rank as one of the fine arts, and to excel in its practice requires genius quite as imperatively as excellence in painting or sculpture, architecture or music. Without such genius as operant, however skilful in manipulating and in the merely mechanical accessories of his profession, can never be higher of other than a simple mechanic therein—that is, however handsomely finished, his pictures may be, they must ever want that life-likeness, as that expression which announces the individuality and personal identity of their originals.

Let me not, however, be understood as underprising great care and skill, coupled with the utmost attainable finish in the accessories above named.

According to the familiar adage, a complete man should have "a sound mind in a sound body." Not less imperatively should a perfect photographic portrait combine a vivid expression of the sitter's soul with the utmost finish in the representation of his person.

I regret to say that numerous photo-artists are exceedingly defective in the mechanical appliances of the art, as well as in a point more important still. How, in fact, could it be otherwise, when from the urgent press of competition, the "cheap system" has intruded into this as well as into all other vocations, "sacred or profane?"

The "go ahead," hurry-scurry movement of our American life is bitterly hostile to high excellence here, as well as everywhere else; for it is manifestly impossible to expend much care and time—even where ability and skill are not wanting—upon pictures which are vended for but a trifle more than the cost of materials used.

The public, it should be frankly and boldly stated, are very culpable in this regard. Precisely so long as they prefer and insist upon having cheap wares, such cheap wares will be promptly furnished to their order, but their intrinsic value will invariably keep even pace with their cheapness. In order to procure a first rate article, whatever its kind, a liberal pecuniary compensation must be paid, since, by a sad but inexorable necessity, artists are absolutely compelled to eat and drink, to wear and house, exactly like the "rest of mankind." Enough on this topic.

Let me remark, however, with the utmost emphasis, that however important may be the mechanical "getting up" of a picture, there is one thing more important still—so important, indeed, that, where it is lacking, a portrait is virtually no portrait at all of a living creature, but, to say the very best of it, the faded representation of a lifeless being. In the "one thing" mentioned, I allude of course to what I have named "expression," a term whose signifi-

cance is so well known to my readers, that they need no explanation of it from me.

As I mentioned above, to communicate this "expression," whether produced by the sun-pencil or any other pencil to a portrait, be it of man or be it of nature, genius is indispensable.

Does my reader ask what I mean by this term "genius?" My inevitable reply is, that I—however it may be with the wiser sort—am wholly incapable of confining that subtle essence within the boundaries of a verbal definition. Its effects, however, I, like all others, can recognize at a single glance. So far as I can comprehend it, it would seem to be a faculty originally bestowed by the All-Creator—susceptible, indeed, of being developed, improved, and exalted immeasurably—but by no possibility to be acquired by one in whom its germs were not implanted at the first.

It acts in ways and towards issues which not even its favoured possessor can explain to others, or even to himself. As simple matter of fact, however, he is qualified to perform by a seeming intuition, and on the instant, what those otherwise organised are unable to do by the most laborious and protracted effort.

It is the Divine Agent, universally, in discoveries and inventions in all spheres.

In the fine arts, however, its agency is absolutely indispensable. Without its unmistakable presence, they are not fine arts, but coarse arts. All, therefore, who are not vividly conscious of possessing this magic gift—be their general abilities and talents as ample and as various as they may—would act most wisely in eschewing all endeavours to master and practise these arts.

Not for a moment, however, would I counsel them to let such abilities and talents lie idle. 'Tis to act were treason to their own endowments, to say nothing of ingratitude to the munificent Giver of the same.

But surely they may readily find innumerable spheres in this topsy-turvy world to which their peculiar powers are specially adapted, and by labouring in which they may acquire a grand and spotless fame for themselves, while they render essential service to their race. In this sphere, however, among the fine arts, they are, most assuredly, "not at home."

Now to the portrait poser, the art student, possessing natural genius, who should have the sole control of the sitting department and management of the camera, I would offer some suggestions as to the means to be adopted by the photo-poser to overcome the difficulty arising from the rapidity with which the sunbeam acts upon the plate.

The portrait painter (as I have said in former articles) may have several sittings, each lasting for an hour or more, and thus have time to learn what is his sitter's most characteristic expression—or, perhaps, to call up that expression by his conversation and personal influence.

The photo-artist has his sitter with him but a few minutes, or it may be seconds, and even then the circumstances are such as not to be very favourable to producing in the sitter's mind the mood which will give his face and figure the best expression. What can the sun-painter do to counterbalance these disadvantages? As I have said more than once before, he must have genius as a *sine qua non*, for this will not only spontaneously suggest various expedients to be used, but it exerts upon those coming in contact with it a kindling, genial influence, which can be neither analyzed or defined.

But genius, without the cultivation which supplies it with materials and implements, can accomplish little. Let us note, then, some of the means to be used in effecting the end alluded to.

In the first place, then, the ambitious and would-be successful photographic art poser should have his rooms and studio so arranged as to act favourably on his sitter's mind, prior to, as well as during the sitting. It will be

* St. Louis Practical Photographer.

understood, without my going into detail, that he should fit up his rooms with artistic taste, having therein books, pictures, engravings, sculpture, &c., of a kind to attune the visitant's mind to the mood he would wish to express in the portrait to be taken.

In furnishing of the apartments, &c.—in short, all of the items of equipment—should be regulated with a view of awakening in the visitants the best and highest thought and feelings.

If I were speaking to common-place, prosaic persons, I might expect ridicule in requital for these remarks. But you, Mr. Editor, and your readers generally, I trust, have sufficient knowledge of human nature—or, in other words, philosophy—to know that we are very much in character what the circumstances about us have moulded us to be. The dark or the bright, the black or the white around us, cast their peculiar shadows upon our minds, whether we be permanently or temporarily under their influence. As the end we are supposed to be aiming at is to get from the sitter his best expression, and as all surrounding circumstances operate in one way or another to affect the mind—whence the expression comes into the face and figure—let us make all he sees or comes in contact with, in the heliographic studio, tend to produce upon him the influence we desire. I need not enlarge, or go into details upon this subject, since those who can understand it at all will understand it at once, and fill up the outlines here given from their own minds.

The previous preparation having been made, we now come to the time of sitting itself. And here, as I have repeatedly intimated, a momentous task falls upon the artist who would get a portrait expressing the best and highest phase of the sitter's character.

I might fill many pages with a detail of what experience has taught me in reference to the position the model (sitter) should be required to assume—the mode in which the light should fall upon his face and figure, so that blemishes may be alleviated, and good points brought distinctly into view.

In short, a thousand things respecting the configuration and locality of the sitting-room, the windows through which the light comes, &c., all of which myriad particulars bear directly and essentially upon the fact whether a mere mechanical transcript, or a mimic life reduplication of the sitter, at his best, is to be obtained.

It seems to me strange that in all the numerous and excellent treatises on our art, scarcely the slightest attention has been given to the subject, which is by far more important than any other—that is, the means to be employed for getting the sitter's best and individualizing expression—his living, thinking, feeling self, instead of a face and form which make us

"Start, for soul is wanting there."

At present, however, I must restrict myself to a few words on a single point—the action of the artist upon the sitter at the moment of taking.

The photographic poser should possess certain conversational powers, together with a certain kind of manners and deportment, whereby he can adapt himself to his sitter—whoever and whatever he may be—with such effect as to call up in such sitter his best and most characteristic moods; or he should instantly quit the position at the camera for some very different employment.

You will find, in looking over the biographies of all who have been distinguished in portrait-painting, that they have uniformly been distinguished by their powers of conversation. To possess such powers demands, first, original genius—involving a ready sympathy with persons of all temperaments and characters; and next, an assiduous cultivation of such genius—a cultivation which puts one in possession of all those myriad methods, both in the way of solid and of graceful, whereby the hearer's mind is aroused and his heart set all aglow.

Therefore I would say that the photo. art-poser who

would be truly such—who would do honour to his profession, and not do discredit to that bright orb who lends his luminous pencil for his work, exacting nothing in requital but a fitness for the profession assumed—must know at the outset that he possesses a conversational capability, and then must cultivate such capability to the highest possible degree.

I need not specify how he is to do this—his own spontaneities will prompt him. It is, however, obvious upon the surface that a fair acquaintance with books of the rarest quality is one important item for such culture.

But more important still for him, as, in truth, for all men else, it is to observe—observe all men, of whatever class or character, with whom he comes in contact—observe them, too, with that genial, humane feeling which so acts upon all coming within its sphere as to summon into activity whatever is best and noblest in them, and to bring into view that imprint of the Divine Original and Sire which is stamped on every soul, though often hidden by the rubbish of worldliness, or covered by the black fetid waves of illicit passion and appetite.

Thus mingling with men of all degrees and qualities, the photo. poser learns how to approach and commune with all—and thus is able to act upon his sitter, both by his conversation and his mere personal presence, as to bring out the expression desired.

TRIMMING PRINTS BEFORE TONING AND FIXING.

MR. JOHN L. GRIMON has the following remarks in our Philadelphia contemporary:—

"The cutting of a print after it is removed from the pressure-frame, and before it is toned, cannot, I think, be too strongly advocated. There is every reason in favour of the plan, and none against it that I know of, except an occasional plea of want of time. I was myself much prejudiced against so flagrant an innovation upon time-honoured customs until observation and an experience as to the economy of the measure made me realize its advisability.

"The clippings from the edges of prints, no matter how inconsiderable they may be when singly considered, become really valuable when weighed by the pound. The pennies that are inconsiderately thrown away would be the making of dollars if gathered together.

"No smaller an item is the economy of gold in the toning process, and, contrary to the preconceived ideas of the uninitiated, there remains the lessened liability of damage to or the tearing of the print during its manipulation. The clear cut edge is a great protection to it. Otherwise, if it is desirable to dry off your pictures before mounting them, it is necessary either to hang them up, to lay them upon covered stretchers, or to place them between heavy blotters or cloths.

"The last plan was the one most generally adopted by the 'Company.' It had the advantage of preserving the pictures well straightened out, and thus rendered more adaptable to the Robinson 'trimmer' or Bergner cutter. Care must be taken that the blotting-papers or cloths are kept scrupulously clean, and an occasional test might be used for the discovery of any trace of soda contained in the former, and the latter should be washed frequently. It is often averred that the blotting pads as they are received from the paper-makers or stationers are already contaminated by soda used in their manufacture. Frequent experiment has, in my own case, failed to detect its presence.

"Even in this apparently minor part of the business more care should be used than an untrained lad generally feels incumbent upon him. The dropping of a print upon the floor, or the use of a dirty clothes-clip, or a soiled paper, will most undoubtedly be ruinous to the photograph. In short, an artist's anxiety about the welfare of his productions is never at an end—no, not even when they are lost to his sight, and become the property of his customers."

LIGHTING THE FIGURE.

PROBABLY every portraitist is well aware that lighting the sitter is a matter of great importance in photography; but it has probably occurred to few to remember that it is the matter of primary importance in the presentment of a portrait. Outline may of course indicate a form, without light and shadow; but the only mode of presenting the image of an object in a solid form is by means of light and shadow, and it is on the proper arrangement and gradation of light and shadow that truth in delineation as well as pictorial beauty depends. The skilled master of light and shadow produces the truest and most natural looking of portraits, as well as the most pleasing and effective pictures. Hence, although the subject has often received attention in photographic literature, it can never receive too much attention; its principles can never be too much enforced, nor can they be too assiduously studied.

During the last two or three years many portraitists have been in the habit of receiving advertising circulars announcing the publication of a pamphlet on a system of lighting by Mons. Klary, a photographer of Algiers, and rumours of the system discovered and described by the Algerian portraitist have reached many who have not seen his circulars. The first thing noticeable in these circular announcements was the enterprise of the thing. Each circular consisted of two or three sheets of closely printed matter, and the names of most of the distinguished photographers in Europe appeared in connection with testimonials as to the value of Mons. Klary's system. The original price of the pamphlet was, if we remember rightly, two hundred francs, equivalent to £8 sterling. After a lapse of time it was reduced to one hundred francs, and finally to fifty francs, or £1, the price at which it is now offered to photographers. The price seems and undoubtedly is, high. But we think it is very probable that the work has proved worth the money to many, as it does beyond a question contain valuable instruction and advice, and the fact that the price was high will in many cases probably enforce more attention to this instruction than if it had been obtained at a low price. Some time ago our esteemed correspondent, Mr. Charles Waldack called attention to the pamphlet, and explained in our pages that the system resembled that described by Mr. Carl Meyer, in America. The system is one which we have often brought before our readers, and advocated. It is mainly dependant on the use of portable screens for reflecting or intercepting the light, so as regulate and direct the proportion and position of light and shadow. An article we wrote and published precisely three years ago will interest some of our readers if they refer to the eighteenth volume of the News.

Regarding the aim of M. Klary to improve the pictorial character of photography as worthy of approbation, we have not hitherto felt it fair to epitomise or make extracts from his pamphlet. As we find this has already been done in some quarters, we feel now the less hesitation in giving some account of the contents of the brochure, without still wishing to interfere with its chances of circulation. In an interesting opening chapter on the importance of light, in the course of which we are pleased to note that M. Klary has studied Mr. H. P. Robinson's work, we find that the author condemns the use of much side-light, by which he says "the beauty of the eyes is seriously threatened, the natural shades of the face are partly destroyed, and the features appear distorted, feeble, or unvigorous. The mouth, that part so graceful and essential of the head, in a woman, the mouth, round which so many feelings are playing, loses nearly all its charmingness; the slight shades which stamp its corners disappear; the upper lip is nearly as light as the lower lip. The shade which should be showed under the latter does not exist, and in many cases the whole becomes white, as far as a thing can be white and still maintain some appearance of shape." As in our experience the most satisfactory portraits have been produced in studios with abundance of side-light, we may here point out an omission in M. Klary's estimate of the case. A top light undoubtedly most readily lends itself to force, and to striking pictorial effect; but it is the side-light which gives natural and satisfactory portraits, and that because it is that lighting under which we usually see the faces of our friends. The windows of ordinary rooms are side-lights, and this is the light which is most common and familiar. A high side-light answering to the upper part of an ordinary window generally gives at once a natural and pleasing portrait if used with anything like judgment.

M. Klary proceeds in his next chapter to insist on the balance of light, so that the lightest part of a face shall not be white, nor the most shadowed part black. He remarks: "There are three sorts of lights in use for the production of photographic pictures: the diffused light, the direct light, and reflected light. The diffused light is that which is employed in largest quantity; the reflected light is that which must be more restrained. A diffusion of light on the whole face makes it appear flat and unvigorous. It is then that the direct light comes to our help in lighting the prominent parts of the face; but it is necessary to employ it judiciously, understandingly, and in small quantity. In order to be really useful the side light must be taken on a level with or above the horizon. The most competent artists agree that the best light is that which falls on the sitter at an angle of forty-five degrees. The relative proportions are never to be, in any case, a matter of chance or accident." The fault in lighting which is most common, and which M. Klary most deprecates, is flooding the sitter with too much light, to the destruction alike of texture, modelling, and pictorial effect.

In another chapter the author proceeds to examine the various modes of controlling light which have been proposed—not simply the ordinary methods of using curtains, &c., but the reflector and counter reflector of Kurtz; the alcove background of Adam-Salomon, first published in our pages; a movable room, proposed by a Hungarian photographer, M. Gondy; and the hand-screen of Kent, which he considers the starting point of his own system. We may here remark, that we have no doubt that the system of lighting with the use of screens has been worked out by M. Klary for himself; but he scarcely appears to be aware that the use of portable screens for controlling the lighting of the sitter is a very ancient device in photography, in common use amongst the early Daguerreotype artists. It has, singularly, and unfortunately, as we think, passed out of common use; but we hope will be, with M. Klary's aid, revived again. A study of his system,

with the diagrams given, will have the effect, we think, of inducing many at least to give it a trial.

Without the use of M. Klary's diagrams we could not well explain his method of using translucent screens for softening light, and opaque screens for reflecting light; and we must take leave of his pamphlet, therefore, by stating that the subject is treated with much intelligence and earnestness, and will well repay perusal. But we may add here, in relation to the subject, that Mr. Cussons, of Southport, who some years ago commenced the manufacture of portable screens for governing light, has recently further developed the matter, and supplies screens on the plan adopted by M. Klary, of Paris, of whose pamphlet a synopsis is given in a circular recently issued by Mr. Cussons. As this is very well done, we reproduce part of it for the benefit of our readers. The circular proceeds as follows:—

"Light and shade giving us all our effects, our ability consists in using both in such proportions that we obtain at will the most varied effects. The top and side lights together are generally adopted in the construction of photographic studios; but it is in the injudicious use of the latter, especially when employed in too great a quantity, that many fine effects are lost, and the resulting picture is rendered flat and feeble, the natural shades of the face destroyed, the features distorted, the eyes, the mouth (the upper lip especially) shorn of their full expression, and the whole face wanting in graceful and natural relief. For heads and half length portraits it is quite unnecessary to use the side light in so large a quantity as is usual; the top light, when under judicious control, will give the better and more artistic effects of light and shade. In order to be really useful a side light must be taken on a level with or above the horizon; the best light is one that falls on the sitter at an angle of 45°. It is necessary that the light be balanced in accurate proportion, the time of exposure sufficient to set forth the lighting, and the development adjusted according to the exposure. The lighting of the face should be balanced in such a way that the contrasts may not be simply black and white, but a soft gradation of all the intermediate tones, as well in the lights as in the shadows, so as to produce a graceful and artistic picture. There are no pure whites to be depicted in the human face, though there are some portions which may be nearly so; the whole face should be more or less shaded, and some luminous touches be slightly thrown on the most prominent parts; the greatest distance from the eye of the beholder should be darkest in tone,—the nearest portion the lightest, and every gradation between.

"Of the three lights used in the studio, the diffused may be employed in the greater quantity, the reflected must be more restrained, and the direct used more sparingly and judiciously. The position of the sitter should be under the principal or strongest light. It is best to employ a soft and slightly diffused light, combining in due proportions the top and side. This is readily obtained by use of the head screen (which, being constructed with various movements, will enable the operator to have this light under perfect control). It should be placed by the side of the sitter, nearest to the light, and of course outside the focus of the desired picture. It must be elevated above the head, raised or lowered and turned to the required angle until the operator observes the true and best effect upon the shades and lines of the face. There will now be seen a general and diffused light over the whole of the figure, but a little predominant on the side nearest the light; then open a small accidental side light quite in front of the sitter, which will fall upon the prominent parts of the face; if the eyes are sunk deeply, lower the screen a little, and move it slightly towards the shaded side of the face; it will thus increase the top light, and bring the face into bold relief; the shaded side, though slightly darker than the other, will remain soft, and full of detail.

"Observe that the reflex of the eyes must be the same in each: these luminous points have their place on the upper part of the eye, and nearest the side light—not in the middle. If the reflex appears in one eye only, the face is too far away from the side light; then move your camera and turn the face towards the side light until these luminous points appear on both eyes; the head will then be well lighted, and the classic outline of the nose well rendered. A beautiful and often unforseen lighting will be discovered by the movements of this screen. Being made of translucent materials, it softens, filters, and slightly diffuses the light over the head of the sitter, and is an immense power in the hands of a skilful operator for obtaining in any studio those fine effects of light and shade which produce a perfect picture, and which could not be easily produced by any existing arrangement of blinds or curtains. With taste and a little practice its use will become intuitive.

"It is necessary to soften the edges of the shadows, in case of need, with a pure and delicate reflected light; this is done very readily by means of the concave reflector, used in accordance with the judgment of the operator. It should be turned towards the sitter in such a manner as to throw a concentrated light upon that part of the face under and behind the eye, as well as the darker portions of the neck, and you will thus avoid the spot of reflected light appearing in the eye. A perfectly exact position of the reflector is as essential as for the head screen, in order that the proper balance of lighting may be obtained.

"For lighting *a la* Rembrandt do not change the position of the face, but move your camera so as to obtain a view of the other cheek, and, with some slight modifications of the head screen, this lighting will be as perfectly rendered as the other; it is not here necessary to use the reflector; the head screen alone will regulate the top light, which must be used sparingly, so that it does not fall upon the points where the middle tones are wanted.

"It is desirable in all studios to provide some object upon which the eyes of the sitter may be directed, and rest easily, at the point of vision selected by the operator; for this purpose we make a small stand upon which is mounted an object to be raised or lowered at will, and fixed at any given point. The semicircular or alcove background of M. Adam-Salomon will prove a most valuable adjunct in a studio sufficiently large to admit of its free use; for by it we obtain the true effects of light and shadow in proper contrast with those of the figure; and hence the subject is brought out in bolder relief than it would be with a plain, flat background. But in ordinary rooms, where the space is so restricted that an alcove background could not be advantageously used, we should recommend a flat background, graduated from top to bottom, from light to dark, and these, if artistically painted, will prove most effective and valuable."

ON THE IMMEDIATE AND POSSIBLE EFFECTS OF CERTAIN RECENTLY PROPOSED ADDITIONS TO THE NEGATIVE BATH.

BY W. HOWARD.*

In the concluding paragraphs of the preceding contribution it will be noticed that while Mr. Munger's assertion regarding the chemical clearness of negatives obtained from his so-called "hypo nitrate" bath is admitted to be absolutely true, no explanation of its cause is given. At the time of writing the matter was to my mind so self-evident that an explanation seemed an unnecessary and impertinent demand upon the reader's patience. Practical photographers having frequently but little time to spare for minute enquiry, I have, for the purpose of being perfectly explicit, before quitting the subject, noted down my impression of that cause by way of addenda.

* Continued from page 376.

The fact that sulphuric acid exists in a free state in the bath is sufficient to account for the clearness of the development. It, as is well known, acts as a very powerful restraining agent, and it is to this property of the acid that the clearness of the chemical effect is really due. Precisely the same effect can be obtained by the addition of sulphuric acid to the developer, and without even the most remote possibility of introducing sulphate of silver into the bath. Again, the "hypo-nitrate" bath is objectionable, because, containing such a powerful restrainer, it materially lengthens the exposure required.

Mr. Eliot's* proposed and practically tested method of working with a bath in an alkaline state is, though not so recently brought under notice, quite as startling and in opposition to generally accepted theories as the treatment with soda hyposulphite.

The mode of proceeding recommended by Mr. Eliot, who has had something like two years' experience to which he can appeal in supporting his assertions, is very simple. Instead of adding silver iodide to the nitrate bath, he saturates it with silver carbonate. This treatment, as a matter of course, renders the bath distinctly *alkaline*.

The advantages which Mr. Eliot claims for his method are very considerable—briefly, freedom from fog, pinholes, and stains. I have at various times used a bath prepared in the manner pointed out, and can say from personal experience that it possesses all the good qualities claimed by its originator. Whether chance or design led to its adoption by that gentleman I know not, but certainly it is the most useful of late improvements in working.

The first surprise in connection with this bath is that, though alkaline, it does not give foggy pictures. Mr. Eliot attributes to the neutralizing effect of the collodion he uses this immunity from the trouble named.

Beyond question, that does act as a useful safeguard, but it is to the nature of the alkaline body present that, for my own part, I attribute the unexpected freedom from fog, because even if a new collodion be used with this bath, clean negatives are obtained.

It may be laid down as an axiom that oxide of silver is the alkaline body present in baths giving foggy negatives. This body, being present in nearly all newly prepared baths, endows them with this objectionable property, and necessitates the usual addition of acid to remedy the defect.

How does oxide of silver make its appearance in a new bath? This is a question worth attention, and answering. If fused nitrate be employed for making up the negative solution, it may be taken for granted that unless that salt has been prepared in a very cautious manner, some portion has been reduced to the state of oxide in the process of fusion. This is especially true when the nitrate has been prepared from silver containing an admixture of copper. To eliminate this, fusion at a considerably elevated temperature is resorted to, and oxide and nitrite of silver are formed by the partial decomposition of the nitrate.

When a bath is prepared from crystal nitrate with common water it is always necessary to sun it, for the purpose of clearing the solution. By this sunning process the water is deprived of the organic matter which it contains; some of the nitrate, being by its agency reduced to the state of oxide, falls down as the well-known black sediment. Some of this, of course, enters into solution; the result is a nitrate bath, rendered alkaline by silver oxide.

Again, in an old bath which has turned alkaline with working, a similar process has been in operation. The alcohol and ether imparted to the solution by the immersion of the plates have reduced some portion of the nitrate to the condition of oxide, and the result is a tendency to fogging. This defect is most likely to occur when working with a collodion containing a large proportion of ammonium salts, as the nitrate of ammonium produced by their decomposition

has the power of causing a much larger proportion of silver oxide to dissolve in the bath solution. Nitrate of ammonia has precisely the same effect in relation to silver carbonate, and it may be advisable not to use ammonium sensitizers for a collodion intended to be employed in working an alkaline carbonate bath, though if the bath were occasionally distinctly acidified with nitric acid to destroy any oxide which might have formed in it, afterwards neutralizing the acid with more carbonate, I would not apprehend any danger from the increased solubility of the latter silver salt.

The lability of oxide of silver, when present in the bath, to give foggy pictures, is traceable to its aptitude for reduction. As soon as the developer is poured on, the picture flashes out almost instantaneously, but also the oxide reduces with alarming rapidity, and, unlike the less reducible free nitrate, attaches its product to the whole surface of the plate. Carbonate of silver is not so easily affected by reducing agents, and it is to this comparative neutrality to reducers that I most attribute the circumstance of the non-production of fog on plates sensitized in an alkaline carbonate bath.

Another and important advantage connected with the use of such a bath is that it permits of much shorter exposures than an acid bath. Acid in the bath, though unavoidable under the general system of working, is not desirable, because it retards very materially the actinic action in the camera. Now by this process it is very easy to get rid of free acid existing in any bath, and since no care is required in respect of not passing the neutral point—indeed, the reverse—the idea must commend itself to the practical man.

I was for a long time doubtful about a carbonate bath evading the pinhole nuisance, but I am thoroughly convinced that it does so, and further, I believe I have discovered the reason of that power possessed by it.

My old system of working was to prepare a bath with fused nitrate prepared by myself, dissolving in common water and sunning, or else in water which had been previously treated with a small quantity of nitrate, sunned, and filtered. The latter is a very old but thoroughly reliable and useful "dodge." It yields a water (or rather a very weak solution of silver nitrate) perfectly free from chlorides and organic matter. This is more than can be said of commercial distilled water, which generally contains both, and always the latter impurity, and any solution of nitrate made in it will be reduced by exposure to light; it is also comparatively expensive. By always keeping some silvered, sunned, and filtered water in stock, it is easy to produce a working bath at a short notice, or in case of accident.

When I had obtained the clear solution of bath in the manner stated, I always found it to be somewhat alkaline and foggy inclined, through containing some silver oxide. This I got rid of by the cautious addition of very dilute nitric acid till exact neutrality was reached. Then the bath was, when iodized, ready for use; but while abhorring heartily the amount of acid which would sometimes accumulate when using red collodions for copying, and likewise disliking the troublesome plan I then had of rendering the bath alkaline with silver oxide, and subsequent neutralization with dilute nitric acid, I gave Mr. Eliot's plan a trial, and am not inclined to give it up now. I still pursue the plan of adding nitric acid after dissolving the nitrate, but don't mind adding excess, because when the carbonate is added it first neutralizes that acid, producing some nitrate; the excess renders the bath alkaline. Those who think of adopting Mr. Eliot's plan would do well to acidify with nitric acid before adding the carbonate, or else this may lay upon the process the odium of having produced fog, when in fact that defect was due to oxide existing in the bath prior to the introduction of the carbonates.

Having worked the process for some time, I was puzzled by the non-appearance of pinholes. According to Mr. Eliot it is not necessary to iodize an alkaline carbonate bath: the natural inference made from such a statement is, that such a bath cannot dissolve iodide of silver. If such were indeed the case, it would be easy to understand why

* By an oversight I substituted the name of Mr. York in my last.

the expected nuisance did not occur. Carbonate of silver does not form a compound with nitrate; or, if it does, it is very readily decomposed, and cannot be made, by any device with which I am acquainted, to crystallize either in the bath or upon the plate. An ordinary thirty-five or forty-grain solution of nitrate dissolves so little of the carbonate, that it is scarcely troubled by even very copious additions of water, provided that the water used be free from chlorides. Knowing that to be a fact, and having confirmed my knowledge by actual experiment, I anticipated that such a solution must be capable of dissolving some quantity of iodide out of the plates immersed in it. In consonance with this view of the matter, when I had used my first alkaline carbonate bath for some time, I took out a portion, and diluted it with pure water. As I had expected, I was rewarded by the appearance of a bright yellow precipitate, but not so copious as in the case of an ordinary non-carbonated bath. This precipitate, upon the application of suitable decomposing agents, gave to starch the characteristic iodine-blue, unmistakably proving its character.

Still, although the bath was kept at work (not being allowed to become acid), and must have been accumulating iodide, the pinholes held aloof. Of course, I was in a state of wonderment about the strangeness of this phenomena. The only reasonable supposition that occurred to me as explanatory of this unusual reversal of effect while the cause remained, lay in the probability that the iodo-nitrate could not crystallize while the carbonate was present. My first experiment was the addition of an excess of nitric acid to my bath, upon which I obtained negatives full of pinholes—proof number one in support of my theory. The next step was to make a strong solution of silver nitrate, saturating it with silver carbonate, and afterwards with silver iodide; then I filtered and boiled it down till but a third of the original volume remained; the remaining solution was allowed to stand for several days, but no formation of iodo-nitrate crystals followed—proof number two, and, I fancy, a conclusive one, both in support of my theory, and Mr. Eliot's assertion that his bath has no tendency to produce pinholes. I have made several verifications of this experiment—both with bath and special solutions, but never obtained any iodo-nitrate crystals.

In conclusion, I would say that, while the plan of adding soda carbonate is quite effectual in imparting carbonate of silver to the bath, it would be better to prepare a stock of that compound, and add it directly to the bath, thus avoiding the introduction of soda nitrate, which, though not injurious, is unnecessary.

The only real modification of Mr. Eliot's plan that seems desirable is, that in addition to saturating with carbonate the bath should also be iodized, thus preventing the robbery of iodide from the first few plates. My own method is to dissolve the nitrate in a small bulk of water, add excess of silver carbonate, and a few grains of iodide of silver. The strong solution immediately dissolves all that it requires of the two compounds; I then fill up with the requisite quantity of prepared water, which precipitates the excess of carbonate and iodide, and after filtering I am in possession of a bath ready for work.

(To be continued.)

ON THE DEPTH OF PRINTS AND INTENSITY OF NEGATIVES.

BY CAPTAIN ABNEY, R.E., F.R.S.*

IN the NEWS of the week before last a diagram demonstrating the effect of the exposure of uniformly sensitive paper to the action of the same kind of light was shown. Before proceeding further it may be interesting to note the sensitiveness of different silver chloride papers when ex-

posed simultaneously beneath the wheel which gives increasing exposures. The following diagram shows this.

Paper cut from the same sheet was immersed in sodium chloride of $\frac{1}{3}$, 1, 3, and 9 per cent. strength, and floated on a sixty-grain to the ounce solution of silver nitrate. It will be seen that the salting solution is in a geometrical ratio of 3, and that the sensitiveness increases nearly in a geometrical ratio of 2. For instance, if with the paper salted with the 9 per cent. solution the sensitiveness is 1, with the 3 per cent. it is $\frac{1}{3}$; with the 1 per cent. $\frac{1}{9}$, and with the $\frac{1}{3}$ per cent. $\frac{1}{27}$ approximately. This is not meant to be laid down as a "law" on the subject, but it simply works out thus from these experiments. It will be noticed that the solution used for sensitizing is a strong one, and, within limits, it appears that there is no increase or diminution of sensitiveness caused by the strength of the silver nitrate solution. Where there is a large deficiency of silver nitrate, however, there is a marked alteration in the curves.

The annexed figure shows the alterations that occur, the exposures being graduated as before. Curve A is a standard curve; curve B is due to floating a 9 per cent. salted piece of paper on a fifteen-grain solution of silver nitrate; curve C shows the loss of sensitive-

ness due to paper salted with a 3 per cent. solution of chloride floated on a sixty-grain bath, and afterwards thoroughly washed; whilst curve C shows the effect of albumenized paper sensitized and also thoroughly washed. But few remarks need be made on this diagram, as it speaks for itself. The chief lesson to be learnt is, that for each strength of chloride (and albuminate) there is a limit, below which it is not safe to reduce the strength of the silver nitrate solution. I should rather be inclined to fix the latter at two-thirds the strength of the former, though I write with some hesitancy on this point. Unless fuming the paper be adopted, or some chlorine absorbent be substituted for the silver solution, washed paper is evidently likely to want in depth.

In the next diagram the curves are also due to different exposures. A is that of ordinary sensitive albumenized paper; B, of albumenized paper in which there is no chloride or other salt; and C of a three per cent. salted paper. All were sensitized on a sixty-grain bath, and exposed simultaneously in the exposing-apparatus to a very subdued light. It will be noticed that the blackening of the last is greatest, and of the second the least, whilst the ordinary sensitized albumenized paper

occupies an intermediate position. Evidently, then, besides filling the merely mechanical part of holding the silver chloride in situ, it fulfils an important part in the

Fig. 9.

depth of the print. Comparing the ordinary albumenized paper with the salted paper curve, where the exposure has been shortest, the colouration is least in the former, and falls more rapidly down towards blackness than does the latter. Probably most photographers who have had experience in plain paper prints have found the difficulty of obtaining the same gradation in the highest lights that they have obtained with facility with albumenized paper, and the "reason why" may have not occurred to them. The above diagram illustrates this difference in gradation—if it may be so called—and it may not be uninteresting to seek the reason of it.

The albuminate of silver when exposed to light takes a reddish tint, absorbing the blue. Now, where there is absorption of light there must be work performed in the absorbing body, and in this case the work performed is the chemical decomposition of the organic salt of silver. It is evident, then, that in the top layer of the albumen the darkening will take place very rapidly at first—so rapidly, indeed, that that layer will quickly attain its maximum darkening and red colour. This will cut off the actinic rays from the succeeding layer, and the blackening will proceed more slowly. Silver chloride, on the other hand, darkens to a violet colour, and even the darkened layers allow the actinic rays to penetrate, consequently the depth of colour is attained more regularly than with the albuminate. We now see why the character of prints obtained from the same negative is changed when the amount of chloride in the albumen is varied.

We now pass on to a very much more important point in regard to prints. There is no doubt, as experiment has shown it to be correct—and experiment agrees with theory in this case—that different *qualities* of light affect the curves obtained in a different way. The light from the sun, the light from the sky, and that coming through clouds on a dull day, all differ materially in quality, and when I say quality, I mean as regards the spectrum obtainable from them. If equal intensities of sunlight and blue sky light be taken, for instance, it will be found that sunlight is deficient in certain of the blue and violet rays, which are, comparatively speaking, in excess in the sky-light. This is as might be expected, since the light of the sky is merely sunlight reflected from small particles of suspended matter. The sunlight, after passing through this cloud of infinitely small particles, must be robbed of a portion of those rays which give the sky its blue appearance, and the light from the latter must be richer in these very rays than the former. So again the light from the sky or the sun, after passing through a cloud, must be deficient in certain portions of its components which are absorbed by the watery vapour.

For example's sake, we may imagine that our original sunlight contains one particular blue ray, and one particular violet ray, and that the sky robs it of the violet ray, and allows the blue ray alone to be transmitted, the sky in this case will only reflect the violet ray.

Let both the filtered sunlight and the sky-light now

act upon silver chloride. If the darkened chloride absorb the violet ray much more rapidly than it does the blue ray, it is manifest that the curve of intensity for equal exposures must differ in depth of blackening, and also that if the darkening due to the violet and to the blue, at the extremity of the scale (as given in the diagrams) be equalized, it is also evident that the curves will not be symmetrical. Of course the hypothesis that has been made cannot strictly hold good; every part of the spectrum is present both in sunlight and also in skylight, though there are deficiencies in intensity in portions of each. Hence it is that different curves result from exposure to different qualities of light.

The following diagram gives curves of intensity for light radiating direct from the sun, from sky-light, and from light diffused through a cloud on a cloudy day.

Fig. 10.

The paper employed was ordinary albumenized paper sensitized on a sixty-grain bath. (Curves showing similar differences might have been given for ordinary salted papers.) A (was paper exposed in sunlight; B was paper exposed to a clear sky; and C was exposed in very dull light.

Comparing curves A and C together, we obtain information regarding the printing of pictures on a point which has often been a puzzle to the thinking photographer. 9 in the scale of whiteness is for all intents and purposes practically white—at least, it would be considered so unless absolutely pure white were placed in juxtaposition with it. Running a line parallel to the base to cut the curves, we find that in A it answers to the exposure 0.075, and in curve C to exposure 0.2 of the total. Now, since in a negative the amount of exposure given to paper depends approximately inversely as the opacity of the negative, it is evident that to start with the same purity of white, and to attain the same blackness in the deep shadows, a negative need be less dense in the highest lights if printed in the shade than if printed in the sun; in other words, that the relative opacity of the highest lights in the two cases should be about as 8 to 9.025. Here we have a gain of no small advantage, particularly when it is seen that the negative printed in the shade has the curve which most nearly coincides with a straight line.

To every tale there should be a moral. In the case before us it is this.—You may modify your prints almost indefinitely by altering the light in which you expose the negatives, be it by printing on a dull day, or by superimposing various coloured media. This subject alone is a large one, and should be followed up by photographers by practical experiments.

PHOTOGRAPHY IN AMERICA.

BY NORMAN MAY.

I READ with great interest the experience of your correspondent, Mr. J. C. Stephens, in New Zealand, and doubtless the information he imparts will be useful to many, and prevent some from wasting their time and money in a fruitless search after a photographic El Dorado.

Had I such information regarding the prospects in

America, I should have thought twice before leaving comfortable old England. However, I am not going to write of my own adventures or misadventures, but rather to give my impressions, and what I saw of others' success during a three years' residence in the States and Canada.

The mistake English photographers make, is to greatly underrate the Americans' abilities and numbers; and the assistant often goes to the States expecting to find large tracts of country and dense populations almost destitute of photographers; and should he fail to get a suitable situation, he can, he thinks, easily hang out his specimen frame and do a large business at once. But a month or two in the country will open his eyes. He finds in the large towns that every few doors there is a photographer, and nearly every village of 500 inhabitants has its self-styled "artist."

The American youth, even more than the English one, has an objection to what he considers hard work—i.e., manual labour—and thinks his dyspepsia is greatly owing to his working between meals; so he goes in for a nice light business, in which he can, for a comparatively small expenditure of muscle, get a kind of employment "where the work is put out." He goes to a photographer, pays his premium of fifty dollars or so, and is taught the "whole art of photography" in a month or two, and comes out as a full-fledged operator, colorist, and retoucher.

As an instance of this, I once saw an advertisement in an English journal from an "American assistant, aged 17, who thoroughly understood every branch of the business; salary, £3 3s." Perhaps seventeen was a misprint for twenty-seven or thirty-seven, but whether it was or not, I've seen many similar instances in the States. Five or seven years' apprenticeship would horrify an American. When his short period of tuition is up, he looks about him for a situation in which he can improve himself, preparatory to starting on his own account, and failing to obtain one, in the majority of cases he has a "go in" at once for a little business. It almost seems as though every one who finds blacksmithing or farming too hard work, has a try at photography.

A Canadian photographer of my acquaintance, whose name is not altogether unknown in American photographic journals, had three farmers' sons at one time as pupils. They paid their dollars, learned to take a ferrotype and got a general insight into the business, and a few months afterwards their respective signboards and specimen frames made it known to the inhabitants of some obscure village that a new "artist" was added to the already superabundant stock. Some pupils who start in this way are steady, pushing sort of fellows, and they make their little knowledge go a long way, and though their productions are very inferior at first, they please their customers, and as the average American is more shrewd, as a rule reads more than English photographers, and is altogether, to use their own expression, a more "live man," he gets on by energy; and not being above a hint from more experienced men, in time he is a good hand, and moves to a larger town.

As all cannot succeed, the weaker go to the wall, and I have seen dozens of men who at one time in their lives had their few months and a start at photography only to give it up in disgust, and turn to something for which they were better adapted. So the market is always full to overflowing, and the photographer has many applicants for situations, and, as a consequence, wages are much lower in proportion than in England, while the extremes of heat and cold render the climate at first very trying to English constitutions. I've seen the thermometer 110° (Fahrenheit) in the shade day after day, and in the winter 30° or more below zero, though the air is much drier and more exhilarating than in England; and I know of nothing more enjoyable than a good sleigh ride with a temperature of about zero, or a skate on ice of two feet thickness.

(To be continued.)

OPERATORS AND EMPLOYERS.

A LADY writes to the *St. Louis Practical Photographer* as follows:—

"DEAR SIR,—Will you allow space in your journal for a few suggestions by a lady? My husband was an operator. Thank God, he is no longer. His latest employer was an ancient dame, who thought what she could not see through her gold-rimmed spectacles was of no use or interest; and my husband, while in her employ, had to sink his manhood to keep his situation. Now, Mr. Editor, I wish to make a plea for operators. Why is it that an operator is usually treated as if he were a mere puppet? Is it not the operator whose skill and ability make the reputation of the gallery? If the proprietor is an artist, why is an operator necessary? If an operator is necessary, is there any reason why he should be sunk into nothingness by the proprietor? In my husband's case, while the proprietor could not make a negative or retouch one, she claimed to pose every lady and most gentlemen—to twist them into all sorts of shapes; and if by chance a lady came in and had a sitting without her assistance, her usual comment was, 'I am so sorry I was out; I would have had her sit again.' Now, I humbly suggest to all employers, male and female alike, either do your own operating, or leave it to your operator. If he is not qualified, discharge him and get one who is. If he is, then trust your business to him. If you cannot trust him, how do you expect your patrons to do so? What spirit has an operator to work when at every move he is met by some whim that he must humour, or give up his situation? I have often seen my husband stand waiting with his plate by the camera until it was spoiled, while 'ye ancient lady' was fixing this ribbon or that lock of hair, while a room full of customers were losing patience, time and money alike being wasted, and the confidence of the sitter in the operator utterly destroyed, for the sitter thought so much fixing must necessarily result in a good picture—but lo! the plate was dry and worthless, and the whole thing was to go through with over again. I have seen my husband make from twenty to thirty sittings without missing one; but at the gallery I speak of, the first sitting was usually a failure, until he changed his style and left the plate in the bath until her efforts had culminated in fixing the sitter as straight as a statue and twice as stiff. My advice is, engage a good artist, pay him a fair salary, then lock to him to do good work. If he fail, there are plenty who will not fail; but if you insist on doing the posing yourself, then take the blame when you fail, as well as the credit when the operator succeeds."

The following note is appended by Mr. Fitzgibbon, the Editor:—

"We beg leave to differ with some of the strictures of our fair correspondent. In her plea for operators, she looks, we are afraid, through a more powerful magnifying glass than the ancient dame she speaks of. We emphatically say such ancient appendages have no business in and around a photographic gallery that is progressive. The plea for 'my husband' may be all right and natural; but then there are other operatives besides the husband who who wait watching, supervising, and constantly looking after, if not by ancient dames, by somebody else, to see that they attend to their business right. It is not necessary, because a proprietor understands his business in all its parts, and is proficient, that he should not employ help or assistance, but be compelled to do the work of half a dozen hands, as our correspondent would have him. Again, ancient dames with four eyes are seldom met with in galleries. Some of the principal operators in fine galleries have it all their own way (too much so at times for the proprietors' interest), and many of them know more than the proprietor, and are allowed full sway and management of the same, and are treated in a gentlemanly and sensible manner by their employers when deserving. We believe it to be the mutual interest of both parties to work in harmony together. If

arrogance or ignorance predominate with one or the other, do as I. X. Peck says, discharge yourself or employee, and find another more suitable to your tastes, where there are no ancient dames to domineer over the genius of husbands or any other man."

Talk in the Studio.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—The annual outdoor meeting of this Society will take place to-morrow, Saturday, August 4th, at Hampton Court. The members and friends will meet together at the Mitre Hotel, at six o'clock, to partake of tea.—On Saturday, July 21st, the annual invitation of the President to the members to meet at his house took place, when many availed themselves of the very liberal hospitality which the Rev. F. F. Stitham so genially offers on these occasions, and a most enjoyable evening was spent.

INDECENT PHOTOGRAPHS.—Martha Abrams, 55, and Peretz Abrams, her son, 15 years of age, were charged before Mr. Barstow, at Worship Street, with selling indecent prints and having indecent prints in their possession.—It appeared from the evidence of Detective-sergeant Tew and Detective Vincent, H Division, that the prisoners were in the City Road with a stall, on which were spread a number of photographs, cartes-de-visite, &c., for sale. Some information had been previously given to the officers that the prisoners offered privately the photographs to men. The officers made one or two purchases, and then asked the boy if he had anything else to show them, and he, going to a corner of the stall, beckoned them to him, and then produced a quantity of obscene prints, and sold them to the officers at 2d. each. The boy and woman were then taken into custody.—The magistrate examined the photographs, of which a great number were produced by the officers. There were certain productions of a French character, principally caricatures, but the majority of the photographs were copies of well-known works of art—"Leda and the Swan," "Perseus and Andromeda," "The Greek Slave," &c.—Mr. Barstow was of opinion that the works were indecent within the meaning of the Act, and ordered them to be destroyed. He fined the woman 40s., or one month, and discharged the boy, believing that he had acted under his parent's direction.—*Daily News.*

IMPROVING HEAD-RESTS.—A correspondent of *Anthony's Bulletin* writes:—"Your May number contains a very useful suggestion—from Mr. N. K. Cherrill, of English fame—regarding the construction of common head-rests with two bearing points for securing the upright rods. The suggestion would remedy a serious defect, and should be heeded by manufacturers in future; but it does not help the thousands of head-rests now in use, and constantly giving more or less annoyance, as Mr. Cherrill describes. I am using a simple device involving the same principle, that can be applied to any, and which removes most of the difficulty. I take about twelve inches of copper wire of suitable size, and, bending the centre around the neck of the standard, twist it firmly, and thrust the two ends over and down the empty hollow; thus when the rod is replaced we get the two points of contact, and the consequent firmness, at very slight cost." "E. K. Hought."

SILVERED PAPER is dangerous to leave lying about loosely. It easily takes fire, and can't be smothered out. We know of a gallery last month that came near being no more by the silver paper taking fire while being dried. Scraps and cuttings come under the same head.—*Practical Photographer.*

To Correspondents.

D. H. T.—Rolling machines of the kind you describe generally answer very well for cards, but the result is not the same as that given by a burnisher, as the principle is essentially different. The addition of a steel plate would not make it the same as a burnisher. The burnisher has a fixed burnishing surface, and the picture is carried under it, the picture moving whilst the burnisher remains fixed. The question whether it is worth while to purchase a burnisher whilst you have a good rolling press is one for your own judgment. You know what kind of surface your press will give, and you have doubtless seen the results produced by the burnisher, and it is for you to judge whether it will answer your purpose to go to the extra expense. Weston's burnisher is a very good one.

E. M.—Negatives for transfer from glass should not be varnished, as the varnish often permeates the film, and cements it to the glass, and makes it difficult to remove. In some cases, however, when gelatine is used for transferring, the coating of gelatine, contracting in drying, brings away the negative film with it on curling up and leaving the glass. When leather collodion is used for transferring, when the coating is dry, if the plate is placed in water, the two films will then often leave the glass together.

G. M. D.—New glass, as a rule, only requires washing in water; but if any doubt be entertained that it is greasy, use a cream of rotten stone and alcohol to rub it with. Polish this off with a piece of clean, soft linen cloth, and polish finally with a clean leather. Old glasses—by which we mean those which have been used—should be rubbed with nitric acid; or the following mixture is a good detergent:—

Water	6 ounces
Sulphuric acid	1 ounce
Bichromate of potash	1 "

This should be followed by thorough rinsing.

PORTRAIT AMATEUR.—There are various modes of reproducing negatives. The simplest method is to produce a transparency in the camera, and from that a negative by the wet process, also in the camera. As a rule, however, negatives are better when reproduced by contact printing. The "dust" process, as it is called, produces very capital results. That has been described both in these pages and in our *YEAR-BOOKS*. Contact printing on dry plates, or on collodio-chloride, also answers well.

J. W.—Your efforts have certainly not been successful, and are rather discouraging; but you must persevere hopefully. In the first place, your negative is not good; it is not sufficiently intense, and lacks sufficient contrast. It has been slightly over-exposed. Try a weaker developer, use eight grains of the iron salt, and fifteen minims of acetic acid to the ounce of water. Then you are under some mistake as to your printing. The paper you mention needs no exciting with silver, as it is already sensitive. There appears to be your greatest blunder. You should try at present the simplest formulae. Try the acetate bath for toning. Your negative is not quite sharp. If you use it with the stop the exposure must be considerably increased.

YOUNG PRINTER.—There are various proposed modes of making a silver bath which shall not readily discolour, and the paper excited upon which shall keep a few days without discolouration. In our own practice we find a forty-grain bath made with commercial nitrate of silver, every pint of which contains about three ounces of methylated spirit instead of water, answer well. If the paper be floated not too long, and be drawn over the edge of the dish so as to remove as much excess of silver as possible, it will not discolour inconveniently rapidly. In hot weather, of course, it will discolour much more readily than in cold. If it be required to keep a few days or weeks, the use of washing, or the addition of citric acid, or some other of the appliances recently discussed in our pages, will be found useful. You will find an article describing the various modes of restoring a discoloured bath in our pages a few weeks ago. There is no short cut, no royal road, to photographic knowledge and success. You must read and study what is written on the subject, and acquire experience by personally trying the various methods recommended for given ends.

DESPERANDUM.—The film leaving the plate in the bath may be due to several causes. The use of a horny, tough collodion, somewhat too thick, will cause it; but the most common cause is the use of a very acid bath.

YOUNG PORTRAITIST.—The chief cause of your failure to produce satisfactory vignettes is the use of too dark a background. To succeed well in vignetting, the background screen should be of a light grey tint; it is then easy to secure soft gradation in vignetting the background tint into the white of the margin.

R. F.—The reticulation in your collodion film is probably due to the presence of water, the solvents used having been insufficiently rectified. Some samples of pyroxyline favour this tendency; but the fault is generally in the ether and alcohol. We fear there is no remedy. The collodion may, however, be useful for addition in small quantities to a collodion giving a horny, repellent film, as such a collodion would be improved by the addition.

B. B. S.—We have often endeavoured to impress upon readers the fact that it is impossible to secure a brilliant print with a rich tone of either purple, brown, or black, without a good negative with sufficient intensity and contrast. A thin negative permits only of a thin deposit of silver in printing before the lights are over done, and a good deposit of silver in the blacks is necessary to a rich tone. With a weak, poor negative only grey or light brown tones can be obtained.

B. G.—A gas stove may be used in the dark room if it have a proper flue to convey the products of combustion to the open air. But in any other circumstance it is unwise, as such products are very undesirable in the room.

A LADY AMATEUR will find the screen described on page 100 of our last *YEAR-BOOK*, by our esteemed correspondent, Mr. Norman May.

Several Correspondents in our next.

The Photographic News, August 10, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

THE BRITISH ASSOCIATION AT PLYMOUTH—RECORDS OF GUNPOWDER EXPLOSIONS AND SHOT AND SHELL PRACTICE—THE SPECIAL CORRESPONDENT.

The British Association at Plymouth.—The British Association holds its annual gathering next week at Plymouth. The names of the presiding officers of sections have already been announced some time, and the President of the Association for the present year, Professor Thomson, will deliver his inaugural address on Wednesday evening. The British Association has for some time past been characterized rather as an annual holiday for scientific men than for anything else, and the locality chosen on the present occasion is sure to be popular for this reason, if for no other. The proximity of Plymouth to the playgrounds of the West country is sure to lure many to make holiday in that direction, for North and South Devon, as likewise the whole of Cornwall, are not very far off. Penzance and the Land's End districts are very charming spots for a short tour, the Lizard, Kynance Cove, Marazion, St. Michael's Mount, the Loggan Stone, quaint little Mousehole, and other spots being all worthy of a visit. Photographers will find it well worth their while to take a camera and a few dry plates with them, should they feel tempted to join the meeting of the British Association, and afterwards take a ramble through the country, either on their own responsibility, or under the wing of the officers of the Association. These, as usual, have already made arrangements for the excursion of members to various districts around Plymouth, and to those who are not acquainted with the fact we may mention that those who join these excursions do so at a very moderate cost to themselves. Indeed, it is a very good guinea's worth that one realizes on taking a member's ticket, if a man have a penchant for scientific gatherings and soirées, for beyond the privilege of entrée to all these gatherings, members, as we have said, have the right to join the excursions which have been organized; only, it is necessary, when choice has once been made of the excursion to be undertaken, that the member should secure tickets for the same at the earliest possible moment, since, as might be expected, the favourite tours are much run after, and the issue of tickets is frequently limited. A feature of this year's meeting at Plymouth will be no doubt a visit to the interesting Government works of the seaport. Plymouth has lately given way to Portsmouth as a dockyard, and all our big ironclads, such as the *Inflexible*, *Dreadnought*, *Thunderer*, &c., have been fitted for sea at the latter station, but still there is much to see at Plymouth and Keyham, on the Hoe and at the magnificent Breakwater, which cannot fail to be interesting to visitors to the British Association gathering. The Eddystone Lighthouse will, as a matter of course, be visited, and no doubt any of Her Majesty's ships which may happen to be lying off the port will form the object of another excursion. Therefore, although the British Association may not present such scientific interest as was formerly the case before societies were formed in London and other centres for the discussion of each and every branch of study, there is still sufficient attraction, in one shape or another, no doubt, to make the gathering this year a successful one.

Records of Gunpowder Explosion and Shot and Shell Practice.—It is now some years since the Home Office determined to appoint officers to look after the manufacture of explosives throughout the kingdom, and to make strict enquiries into the circumstances of accidental explosions, with a view to reducing the number of these calamities in the future. The officers chosen were men of some scientific attainments, and it at once occurred to them that valuable teaching might be secured by photographing the scenes of disasters, and in this way secure a truthful record of the effects produced. This step

was sanctioned by the Home Office some time ago, as we took occasion to make public in these columns, and from that time to this the inspectors have made it a feature of their investigation to secure photographic records of the scene. The results of these measures are now becoming apparent, for by a prolonged study of the effects of various explosions, the officers have become very experienced in the matter of finding out the cause, and discovering the nature of the explosive which has caused the mischief. Thus the difference between an explosion of gunpowder and one of dynamite can at once be appreciated by officers whose duty it is to investigate these occurrences, and their information has been in a great measure secured by a study of the collection of photographs obtained from time to time in the course of their duty. A brick wall, for instance, which has been shattered and thrown into a heap of ruins, would at once tell the Home Office authorities that a slow-burning explosive, whether gunpowder or fire-work composition, had been at work; while if the explosion would seem to have cut down a structure as sharply as with a knife, then this is a pretty good proof that some of the terrible detonating compounds have caused the catastrophe, and *prima facie* evidence is at hand that gun-cotton, dynamite, lithofracteur, fulminate, or some such materials have wrought the damage. No draughtsman could record the results so truthfully as the camera does, and as it is here not a question of two or three points, but of the general aspect of the scene, photography is especially suitable. A similar application of the art is made at the School of Gunnery at Shoeburyness, as many of our readers know, where the effects of shot and shell against iron plates and stone casemates are recorded in a similar manner. The committee which is entrusted with the duty of experimenting with guns *versus* armour employ the camera to illustrate the reports made from time to time, and these can hardly be exaggerated, one way or the other, so long as the statements are supported by pictures taken on the spot. Where a shot definitely pierces a target, the daylight let through is at once evident, while we see also the nature of the hole, whether torn or jagged, or smoothly punched out. Not only is a front view taken of the target, but a photograph of the back also shown; and if the shot or shell has penetrated, the damage done to the supports and rafters (which represent the 'tween decks of a ship) is at once evident. Or if the shot has lodged in the target, although from the front no injury is apparent, it is frequently the case that a photograph secured from the rear will show an ominous bulging of the plate, and a starting of the backing. As there are always two parties deeply interested in the matter, namely the gunmakers and the ironmasters who have furnished the plates, it is exceedingly necessary that there should be an impartial judge, and this is furnished by the camera. Only last session there was some ill-feeling raised in the House of Commons on the question of the penetrative power of the so-called "Woolwich Infant," or thirty-five ton gun; and while the Surveyor-General of the Ordnance affirmed, on the one side, that a certain shot had penetrated the target, another member of Parliament, Captain Price, vowed that the projectile had not done so. In this case the dispute was soon settled by a reference to the report of the officer who had charge of the experiments, and a picture of the results, secured by the camera at the time of the trial, forthwith furnished evidence which none could gainsay. In these two instances, then—namely, the record of explosions and of shot marks—photography fulfils a purpose the value of which must readily be appreciated by everyone.

The Special Correspondent.—From Tiflis comes to us news which shows that the regulations in respect to newspaper correspondents with the Russian Armies are being made more strict than was at first contemplated. We remarked some time ago in these columns that the correspondents were to wear an official badge, and to carry a permit bearing upon it a photographic portrait of the correspondent to allow of the person of the latter being identified. Now it appears that

the journalist has to be provided with an endless number of such portraits, to be distributed to all the chief officers or commanders of corps, so that these may have the wherewithal to identify strolling adventurers, of whom, we are told, large numbers are to be found in the camp. Under these circumstances, gentlemen proceeding to the East to act in the capacity of Special Correspondents will do well to provide themselves with a few dozen cartes-de-visite.

SHARPNESS AND HAZINESS IN PORTRAITS.

BY DR. LIESEGANG.*

THE photographer usually looks at his work from quite a different point of view than the public. For what reason does he give over his negative to the retoucher? As in early days the positive-retoucher, so at present the negative-retoucher, is a skilled hand. Not to spot prints is he engaged, but to soften the sharpness of a negative. It is true, photography increases the contrasts, whenever there is opportunity for so doing. High lights are always heightened at the expense of those hardly so well illuminated; the developer also attracts silver from the sides where a white band, a bright cloud, a light-coloured background, are to be found, and the darker parts suffer in consequence. Moreover, in printing, at any rate upon albumenized paper, the higher lights lose something in the toning and fixing baths, while the shadows allow a portion of their details to sink into the paper.

In order, therefore, to present the sharp negative to the public in a favourable light, it is given to the retoucher, who swells the cheeks and softens the hard lines upon it; in a word, everything is equalized when possible, and finally—the portrait is made as unlike as possible.

Why does the photographer make his negative sharp, if he has to have it softened down afterwards? Would it not be more simple to make a soft delicate negative in the first place, and then dispense altogether with the retoucher?

English photographers say, yes. The public asks our English brethren for "soft pictures," and these are supplied. The difference between "sharp" and "harmonious" pictures was once explained to me thus: "Sharp, is the parrot's cry; delicate and harmonious, is the song of the nightingale."

The ways adopted in England to secure harmonious (the German for which is unsharp) pictures are several.

Madame Cameron, of Ceylon,† who has taken a large number of very valuable life-sized portraits of well-known personages with charming haziness, they tell me, is in the habit of telling her sitter at the critical moment to shake his head a bit. Those who have seen the pictures will not entirely disbelieve this story. At any rate, it is certain that Madame Cameron has found many disciples, and that many English photographers supply their customers with hazy pictures, or what we should term unsharp prints, although perfectly able to furnish sharp images if they desired. A striking example of this is afforded by a series of Imperial portraits lying before me now, and which are the work of a well-known London firm.

Like the Cameron pictures, they are soft, fully lighted, hazy; there is, in fact, not the least sharpness to be seen, even in the case of the smallest lines, formerly looked upon as a condition towards good photography. This much is certain in connection with these pictures: no painter can find fault with them on account of any disagreeable "microscopic" sharpness. In the series, however, to which I refer, there are a few pictures of the artist himself who has sent them; they are the only exceptions, and are sharply in focus, so that they seem to say: "I, as a photographer, like sharp pictures, but the public will have its own way, and, therefore, I produce them hazy." At first sight these unsharp pictures do not take one's fancy much, but they grow

upon you after a time, like the water-colour sketches in the English galleries.

It is very certain in any case that photography gives an excessive sharpness, and that all photographers do their best to soften it down: some by retouching upon the negative, others by peculiar methods of lighting, and others, again, having recourse to modifications in printing. In a most singular manner, however, do positive prints secured in this way differ from pictures obtained by the Daguerrotype or Ferrotype process. Especially the latter method in its improved form shows us how to secure prints of a character which leaves the results of the brush very far behind. In my opinion it is a grave error connected with the photography of to-day that a negative is secured first of all in the camera. Colour, as well as the thinness and thickness of the precipitated silver, combine in such a manner that it is often very difficult to determine the printing capacity of a negative as soon as it differs in the least degree in respect to its usual well known qualities. Would it not be much better to secure a good positive in the first place, and to produce therefrom a negative capable of being printed?

Again, were this the case, that a positive was produced in the first instance, this could be at once reproduced, enlarged to life-size, or reduced, as the case may be, and positives in collodion printed off which are very rapidly produced, can be transferred to any kind of material, and are as beautiful as they are permanent. Experiments already undertaken in this direction have, I may mention, proved the possibility of a pure positive process of this kind.

ON SOME SIMPLE LABORATORY MANIPULATIONS.

BY DR. P. TOWNSEND AUSTEN.*

THERE are many little operations performed in the laboratory which, although they are not of great importance, are still often of convenience to the working chemist. Sometimes a simplification or improvement of these little processes may save much labour and annoyance.

Use of Felt Pads in Protecting Glass Vessels.—The destruction of glass vessels is dependent on many causes. The vessel may stand on grains of sand which scratch the glass. If the glass is not well tempered it may sometimes, on being slightly scratched by these grains of sand, suddenly go to pieces, somewhat in the manner of a Prince Rupert's drop. If stone surfaces are used on the laboratory tables, accidents occur continually. Vessels, if not placed very carefully on the slabs, may be struck against them. Or if a glass vessel containing a hot liquid be placed on a cold stone surface, the glass around the bottom is quite certain to crack.

After trying various means of prevention, I found that pads of felt were by far the best mediums for protecting glass vessels.

Felt, about half an inch in thickness, such as is used in restaurants for placing under beer glasses or for roofing purposes, can be bought at a very moderate price. It should be cut up into squares, or, better, into oblong pieces ranging from two by four inches to eight by twelve inches. A beaker filled with a hot liquid—boiling sulphuric acid, for instance—may be placed with perfect safety on one of these pads. The felt is a very poor conductor of heat, and the glass hence preserves its temper admirably. Neither is there enough resistance offered to the glass surface to allow it to be scratched by any grains of sand which may perchance be on the felt. By striking the pads against the table all sand and grit may easily be removed from them.

The softness of the felt removes all chance of breakage, and it is really remarkable how long a set of beakers will last when always allowed to cool off on felt pads.

* *Photographisches Archiv.*

† The esteemed writer would say Isaac of Wight.—Ed. P.N.

* *Chemical News.* The suggestions which follow will prove of service to many of our readers.

If the pads get wet, a day in the air-bath will restore them.

I make it a rule, in my work, to have a pad under every piece of glass apparatus on my laboratory table. If felt cannot be obtained, pads of thick carpet may be used with good effect.

The Elimination of Crystals by the Microscope.—In chemical research the microscope plays an important part in revealing the presence of crystalline substances in solutions. The usual method of preparing substances for examination by the microscope when, as in the laboratory, fine microscopes, animalcules, cage, and other conveniences are not at hand, is to evaporate some of the solution on a watch glass over a micro-chemical gas-flame, and then rub with a glass rod, when the crystals begin to grow on the minute scratches in the glass, and thus set up a general crystallization. The crystals formed in this manner, however, are rarely satisfactory, being often broken, misformed, or mixed with a large amount of the substance in a partially amorphous state.

If the solution be evaporated to the right consistency in a watch-glass, and another watch-glass of the same size, previously warmed, be placed upon it, the drop expands to a film. The upper glass should not be pressed, but allowed to rest of itself. The film is similar to the one obtained in an animalcule cage, being, however, thicker. If now a few drops of ether be placed in the upper watch-glass, the cold caused by the evaporation of the ether will cause a crystallization to take place between the watch-glasses. The growth of the crystals can be quite accurately managed by increasing or diminishing the cold on the surface (by blowing on the ether).

The crystals formed are, as a rule, perfect in shape. I have by these means obtained well-defined crystals from solutions which, by rubbing with glass rods, afforded me only amorphous powders.

FREEZING MIXTURES.*

THE numerous and varied applications which ice has found in these times have greatly enhanced the importance of that product, and, while large portions of it have annually been transported from the colder to the hotter regions of the globe, scientific ingenuity has attacked, energetically and successfully, the problem of producing cold by artificial means for industrial and other purposes. In a recent number of *Dingler's Polytechnischer Journal* Professor Meidinger has an instructive paper giving an account of the progress made in recent years in the art of ice manufacture.

There are three ways indicated by physics in which temperature may be lowered, and ice formed—viz., solution of solid substances, evaporation of liquids, and expansion of gases. The following is an abstract of that portion of Professor Meidinger's paper relating to production of cold by solution:—

Heat is absorbed in bringing solids to the liquid condition; and the cold thus produced may prove sufficient to convert water into ice.

The best known of the numerous freezing-mixtures that have been hitherto described is, of course, one involving ice itself: it consists of three parts of ice, and one part of ordinary salt.

Dissolving concurrently, these two substances give a temperature of -21° C. (the freezing point of the solution). The melting of only a part of the mixture is sufficient to produce this temperature throughout the mass; and with constant admission of heat, and stirring, the low temperature is maintained till the whole is dissolved. The freezing-apparatus of confectioners is well known: a tin pot containing cream, a wooden or metallic vessel inclosing the pot, and the interval filled with ice and salts, which is frequently stirred, that the ice may not sink to the bottom. In a Paris

machine for home use the agitation of the freezing-mixture is maintained by rotation of the double cylinder containing it and the cream vessel round an axis at right angles to the cylinder's length. Professor Meidinger has constructed a machine based on the observation that a solution of ordinary salt under 0° also fuses ice, and, so long as its concentration is maintained, produces the same low temperature as the mixture of salt and ice. He provides a sieve-like vessel, containing salt, to maintain the concentration as the ice melts. The lowering of temperature is uniform throughout the vessel, and no stirring is required. The machine has come largely into use in perfumery.

On the basis of his own experiments, Professor Meidinger has formed a table showing the respective merits of various freezing mixtures. The following extract contains the most serviceable:—

Mixture.	Decrease of temperature.	Specific heat of the solution.	Volume weight of solution.	Loss of heat units.		To use for 120c		Cost in Marks.
				1 k. Mixture.	1 l. Mixture.	Salt k.	Water k.	
1 ordinary salt, 3 ice.	21° 0.83	1.18	125	100	0.5	1.5		0.34 to 0.12
3 cryst. Glauber salt, 2 concd muriatic acid	37° 0.74	1.81	55	74	2.7	1.8		1.0 to 0.6
2 nitrate of ammonia, 1 sal ammoniac, 8 water	30° 0.70	1.20	42	51	3	3		7.6 to 6.8
3 sal ammoniac, 2 saltpetre, 10 water	26° 0.76	1.15	40	46	2.1	4.2		2.6 to 2.2
3 sal ammoniac, 2 saltpetre, 4 cryst Glauber salt, 9 water	32° 0.72	1.22	50	61	2.5	2.5		1.8 to 1.6

Salt mixtures give much greater lowering of temperature than simple salts, as they dissolve in much less water. Thus, one part sal-ammoniac is dissolved in three parts water, and lowers the temperature about 19° ; saltpetre dissolves in six parts water, and lowers the temperature about 11° . (Compare the fourth and fifth on the list). It will be seen that the salt-ice mixture proves considerably more energetic and cheaper than any of the others so far as use of the materials only once is concerned. The second mixture, too, cannot be restored; nor can the last, easily, on account of the crystallized Glauber salt. Both are comparatively cheap, however. The mixture in which, by vaporisation of the solution, the salt is easily renewed in its original condition, nitrate of ammonia and sal-ammoniac, is so costly at the first that it would not do to use it only once. This was the mixture employed in an apparatus first exhibited by M. Charles at the Paris Exhibition in 1867. The tin vessel containing the substance to be frozen is inclosed in a large wooden vessel containing the freezing mixture, and is furnished with screw wings, which stir the mixture as the vessel is rotated. Another form is that of Toselli's *glacière Italienne roulante*. The cream or other such substance is enclosed in a conical-shaped vessel suspended in the freezing-mixture, and the outer vessel, enveloped in cloth, is rolled to and fro on the table. None of these machines have found very extensive use. Large masses have to be operated with to obtain even small results; and the sum of operations must generally prove too troublesome in a private house.

As to the question of manufacturing ice on a large scale

* *English Mechanic.*

by means of solution of salt, Professor Meidinger comes to the conclusion that by means of 1 kilog. of coal (for restitution of salt used) not more than 2 kilogs. of ice can be prepared; not to speak of the machine force required for transport of the large quantity of liquid. This is very unfavourable; an ammonia machine will give four or five times better results. Much improvement is, in the circumstances, hardly to be looked for. It would be necessary to find a salt that, in dissolving, gave a much greater lowering temperature than the mixtures known, and this cannot be expected, since all the known salts have been examined in reference to this point. The real cause of the small productions of such apparatus lies in the fact that restitution of the salt is effected only by change of aggregation (vaporisation), and this involves large expenditure of heat. It may be mentioned that, according to experiments by M. Rudorff, on cold produced by solution of 20 different salts, the two which gave the greatest lowering of temperature were sulphuretted cyanide of ammonium, and sulphuretted cyanide of potassium—105 parts of the former dissolved in 100 parts water produce a lowering of temperature of 31.2° ; and 130 parts of the latter in 100 parts of water as much as 34.5° .

CLEANING AND RESTORATION OF OIL PAINTINGS.

[The cleaning and restoration of oil paintings is a trade in itself, often requiring great skill and experience for its successful practice. But as photographers frequently have oil paintings to copy which may be greatly improved for the purpose by a little treatment, the following extracts from a useful work we have before laid under contribution—*The Camera and Gilder's Guide*—will be found interesting. We would caution inexperienced persons, however, that it is very easy to spoil a painting, and I recommend a little practice on things of little value.—Ed. P.N.]

A few words on the preservation of pictures may not be out of place, as this little work may fall into the hands of those who possess many valuable works of art, who will be glad to receive a few hints on the subject.

Remarks on this subject would not be necessary in some countries, as exposed wall paintings in the Egyptian tombs are as fresh now as the day they were painted. This is attributed to the warm dry atmosphere, amongst other causes, which has preserved the colours in a brilliant condition for thousands of years.

In England the great cause of the deterioration of pictures is the cold damp atmosphere, so prevalent in our climate, and it is necessary where pictures are hung to occasionally air the rooms where they have been left some time without fire.

It need not be mentioned that it is ruinous to hang pictures on a damp wall, but where it is desirable to hang pictures on a wall generally damp, the wall must be lined with thin sheet lead, and papered over with damp-proof paper, before any pictures can be hung.

In a new house especial care should be exercised to make sure that all the walls are dry before trusting any pictures in the rooms.

Where a gallery is provided for the reception of pictures, proper means are used for ventilation and heat, and greater care can be bestowed upon them than is possible in a dwelling house, where, as in a dining room, the vapours from the dining table, and also from gas or oil lamps, are constantly at work at their deterioration; and when conservatories open into apartments, the damp must diffuse itself from the watering of the plants, the damp earth, and other causes. These in time exercise an influence on the pictures in the adjoining apartment, and slowly and insidiously work mischief if not keenly watched and guarded against.

With valuable oil paintings a sheet of colourless plate

glass securely placed in the frame, air-tight from the front and the picture placed so as not to touch the surface of the glass, and secured at the back to keep out the dust, &c. will be found to preserve its brilliancy of colour for number of years. There is an objection to glass oil paintings, as they cannot be viewed so well, owing to the reflection of the glass, but the advantages far outweigh the objection. It would be as well if both pictures and frames were covered up during the cleaning and dusting of the carpets and furniture, but the practice of covering up oil paintings for many months together during the absence of the owner cannot be recommended.

Frames should be regularly dusted with a feather duster. Oil paintings should be taken down at least once a year, the frames cleansed from dust, and also the back of the stretchers. The picture should then be carefully sponged with clean cold water till the dust and fly spots have disappeared. An old silk handkerchief then applied with moderate friction will be all that will be required. On no account use soap or any alkali.

With regard to water-colours, chromos, and engraving the glass should be pasted in the frame, and the picture would be better to stand back from the glass, when the dam and other vapours will not be likely to injure them. We have seen on very foggy days, where doors have been suffered to be open, the vapour condense on the glass and run down communicating with the picture behind, and leaving a stain on the margin. This should be guarded against.

Lining Oil Paintings.—The majority of oil paintings have canvas for a base, and are consequently liable to damage from the ravages of time and accident. A rotten canvas is a common thing, produced oftentimes by being hung in a damp place, and attacked by insects, which destroy the canvas, and, if wedged up in this condition, the result is a fracture across the painting. When pictures have thus progressed to decay, the only remedy is lining or laying down the picture on a new canvas back.

In the first place, clean off any old varnish or dirt that may have accumulated on the painting, so that when the operation is complete, the face of the picture may not be unnecessarily dampened. The picture should then be carefully cut from the old stretcher on which it has been tacked, and it should be then squared up on the four sides. A large smooth sheet of paper should then be pasted over the face of the picture, and if it is a large size, or the canvas very rotten, two or three sheets would be necessary to preserve the painting during the operation from damage. Sometime it will be found advantageous to paste the sheets of paper on the painting before it is cut from the frame, as it sometimes contracts and throws it out of shape. A very smooth table must then be used for the succeeding operations, and the picture laid down on its face, and the back well cleaned of dirt or any unevenness, which may carefully be done with a knife. The picture is then covered very evenly with glue and paste in equal quantities, and a little corrosive sublimate to prevent insects from attacking the canvas, and on a new canvas, quite two inches larger every way than the picture, must be evenly laid down. It must then be well rubbed down by the hand, using as much pressure as possible to make every part adhere. When nearly dry, a heavy heated iron must be passed over the newly-laid canvas to make it perfectly smooth. It will be seen that a very smooth table is necessary, as by this operation every inequality will show on the picture. The iron must not be too hot, should be a good size, and at first be lightly passed over every part, and no heavy strokes on any one part be given, as the object is to bring the picture to an even surface. We have warned our readers not to have the iron too hot, and this caution will be found to be necessary, when the consequence would be a singed canvas and discolouration of the paint. Before using the iron, be careful, if the picture has been painted with thick masses of colour for effect, to lay some fine woollen cloth underneath it, or it will be damaged; but if the picture is smooth the cloth will not be required, nor the

iron so hot. An iron too cold will not effect the object required; the medium heat will best suit the purpose.

A new stretcher should be ready-made, out of dry deal, and it should have a cross-bar to keep the picture firm, and if a large picture, two or more should be used. The stretcher must be made nearly one inch larger both ways, so as to allow half-an-inch margin round the edges. The new canvas with the picture on it may now be laid on the stretcher, and evenly tacked round the edge in its place. Some will prefer to glue the picture round the edges, but with small subjects it is unimportant. When the picture has well hardened, the paper may be removed from the face with a damp sponge; and lastly, carefully rub the face with an old silk handkerchief to take off the last remains of the damp, and drive up the wedges.

Damaged Canvas.—Accidents sometimes occur whereby the canvas of a picture becomes torn or damaged, and it may not be desirable to line the picture. This may be repaired by laying the picture down on its face and fastening a piece of canvas at the back, which, if neatly done, will not show on the face of the picture. For this purpose lay powdered mastic between the canvases, when a hot iron will neatly join the two together. Some would use melted wax for the purpose, but the above will be found superior.

(To be continued.)

A NEW METHOD OF PREPARING CLICHES FOR MUSIC WITH THE AID OF PHOTO-LITHOGRAPHY.

M. ALISSOFF, OF ST. PETERSBURG, INVENTOR.*

At the present times there are two processes in use for the preparation of plates in the printing of music.

The first is like that used for the production of cliches for books, that is to say, the different signs or types used in musical typography have to be set one after another, so as to compose a complete musical stave. As each sign, however, is divided into several characters, this work is so long, and requires in the compositor so much practice and attention, that a cliche for music prepared according to this process is always very expensive.

The second process consists in engraving the notes on soft metallic plates. Although this is greatly facilitated and simplified by the use of special tools and punches, it requires in the engraver a particular skill, only to be acquired by well nigh life-long labour. And yet, even in the hands of the most skilful engraver, it progresses very slowly, as mistakes can only be avoided by the most extraordinary attention. It is difficult to correct minor errors, and those of greater importance—as, for instance, an omission, or a defective arrangement of the bars—is irreparable. In that case there is no alternative but to begin the whole page over again.

The composing process I employ for the printing of music greatly simplifies and accelerates the work.

It may be described as follows:—

Firstly, the staves, notes, and other signs used in music are printed on very thin unsized paper, and arranged in type-cases like ordinary metallic types. This done, the composition is set by simply pasting, first the staves, then the notes and signs, on a sheet of glass in accordance with the manuscript which is to be printed. These different characters have to be affixed to the glass with a gum which has the property of rendering the paper transparent. As a guide to the compositor, I place on the opposite side of the glass a sheet of paper, ruled closely with vertical and horizontal lines, with the aid of which it is very easy to space the bars properly, and to dispose the notes and musical signs on the staves with perfect regularity. More-

over, the characters made use of, being three or four times larger than ordinary musical signs, may be handled with great facility. When a page is set, the ruled sheet of paper is removed from the glass, and by means of photography (letting the light pass through the composition) a negative is taken, reducing the page to the desired size. From this negative it is easy to transfer the composition to stone, and to print, according to the usual photo-lithographic process, any number of copies required.

Should cliches be wanted, the composition would have to be transferred to zinc plates, prepared according to the ordinary method of helio-engraving.

The advantages of this process are the following:—

1. The work of composition for music is simplified to such a degree that no special compositors or engravers are needed; any one, even a child, may do it, after having but once seen it done. I may even say it is no longer a man's work, but rather a woman's.
2. When composing, any correction whatever may be made with remarkable facility and rapidity; the composer has but to unpaste the little piece of paper on which the error has been made, and he is thus under no necessity of beginning the whole page over again.
3. With the same composition stereotypes of any size whatever may be obtained.
4. A page of music printed by this process, far from being less perfect, is even superior to one printed by the ordinary method.
5. A person establishing a printing office according to my plan will avoid the considerable expense commonly incurred in the purchase not only of a stock of metallic signs and characters, but also of engraver's tools and punches.
6. This process may be used with success for the printing of titles in fancy letter, and ornamented with vignettes; and even for the printing of all names and words of maps and plans."

SOME STUDIO HINTS.

BY A BELGIAN SUBSCRIBER.

1. *Plate Cleaning.*—The best plate cleaning solution is the water in which potatoes have been boiled. In this water boil your glass plates, and rinse; you will find them much better cleaned than with soda or potass. Try it.
2. Never make your silver nitrate of pieces of silver which have been electro-gilded. This year we made some nitrate with fragments of a set of teeth gilded by galvanoplastic, expecting the silver to dissolve and leave the gold intact. But it was not so; and the gold seemed to be dissolved with the silver, as it was not visible in the nitrate. When the nitrate was used in the negative bath we tried and found the plate covered entirely with minute pinholes. The bath solution seemed clear and limpid, but when seen in the sun with a ray falling on the bottle, we saw thousands of minute atoms of gold reflecting and floating in the solution. Filtering was no cure; precipitating as carbonate, no cure; as a chloride the particles did not pass the filter, but rested on it. We then converted the bath into metallic silver by copper plates, as indicated by Captain Abney's Manual, and at the first conversion we still found gold in the nitrate.
3. The simplest way for amateurs of reducing silver wastes is to throw the silver containing solutions (except hypo) on sawdust mixed with ash of paper, and then place a Paris clay crucible with a little borax and nitrate of potass: the wood and nitrate of potass will form carbonate of potass (pearlash). When the flux is limpid as water, and black as jet, flow on dry sand; when cool, you will find pure silver. When the sawdust used is not sufficient to black the flux, put in the crucible a wood stick, which will set all right.

THE EMULSION PROCESS IN FRANCE.

EXPERIMENTS IN THE FIELD.

It would seem that the emulsion process is finding considerable favour in France, and the award to M. Chardon of a Government prize for his method of preparing emulsion plates has further added an impetus to its popularity. At the last meeting of the French Photographic Society, M. Balaguy, an amateur, who seems to have produced a large number of successful pictures with the process, exhibited the results of his work to the members, and as his series of photographs were taken on large plates measuring twenty-seven by thirty-three centimetres, they naturally attracted considerable attention. M. Balaguy accompanied the presentation with some remarks which may be of interest to our readers, many of whom would be only too willing to dispense with the dipping bath if they could so with impunity.

"After the very interesting communication which M. Chardon has made to the Society in reference to his new process, and after the experiences of M. Andra, it is not surprising that an amateur should be seduced into trying them. The chief attraction of the emulsion process is the facility of preparation in regard to the production of the plates, for the photographer views with satisfaction the abandonment of all those laborious operations connected with the preparation of preservatives, their application to the collodion film, the washing operations, &c., with which he was previously troubled in producing dry plates. Neither must there be forgotten the inconvenience that arose from working ordinary collodion plates, the transport of baggage, the dust, and the many precautions necessary to the securing of a really satisfactory result. I used to employ either iodised tannin plates, or bromide of silver plates washed in a bath without any preservative. The results I secured therewith were satisfactory enough, but I must admit that the appearance in the field of the emulsion process has made me put on one side at once all these old-fashioned methods, which, in the midst of success, would frequently betray signs that they were not always to be depended upon for absolute security.

"Every year, about this time, it is my custom to make a little tour in the environs of Paris with a photographic apparatus, and I usually carry with me plates which have been carefully prepared by myself in my own laboratory. I stay out until I have exhausted my supply, and then put my apparatus together and return home to count up my gains. This year my outfit consisted simply of some ordinary glass plates, and two bottles of emulsion, of which half still remains. I owe my thanks to M. A.

Chardon for having been able to effect this little revolution in my photographic arrangements, and all will agree with me as to the agreeableness of dry plate photography, in which all that is laborious and time-taking in the preparation of preservatives, &c., is avoided altogether.

"The emulsion I have made use of was prepared in the same way as all other emulsions. I have not, perhaps, followed the formulæ so closely as I should have done; in fact, I have put a great excess of silver in all the emulsion which I have used. This silver—or nitrate of silver, rather—being free, and having nothing to do, as a matter of course disappeared in the successive washings to which the emulsion was subjected. I fully believe that it is this excess of silver which imparts to the film its matt appearance; while M. Chardon, on the other hand, prefers to secure a collodion plate with a brilliant surface. Save in this respect, my emulsion is similar.

"All the plates which I have the honour to exhibit to you this evening have been prepared (or, in other words, the emulsion was applied to the plate) at a distance from home, at an inn or hotel. The latter was never far from the place at which the plates were to be exposed, but, at any rate, under unfavourable circumstances, for I desired that my work should be executed under conditions sufficient to test it. Add to this that at Barbizon, where these plates were exposed, there was at the time an Indian temperature, the emulsion was warm, and on being applied to the glass it naturally (being solvent) evaporated very quickly, producing the waves and unevenness which appear on some of the plates, it will be conceded by all that the conditions were not really good, although for making an experiment they were not bad either.

The first five plates prepared after the bottle had been uncorked gave very pretty pictures, although the film is torn in some places. One of these I exhibit this evening. I attribute the tearing to too large a quantity of ether in the emulsion, which composed half of the solvent employed to dissolve the pellicle. I have the more reason to believe this, since in the second batch of emulsion which I prepared the defect has not shown itself; in this case some of the ether evaporated, and the emulsion was in this way thickened in a measure. The pyroxyline may also have been in some degree the cause of non-success. Upon this point I recommend emulsion workers to follow more implicitly M. Chardon's formula. Nevertheless, I may remark that in case the operator is troubled with tearing of the film, this defect may be overcome by the employment of india-rubber cement along the borders of the cliché prior to development.

In my work I employed a camera measuring twenty-seven by forty-three centimetres, using plates of almost the same size, together with a large wide-angle lens of Dallmeyer's, No. 5. Some of the pictures I show could not be taken with morning light, unfortunately, from the fact that they were unfavourably lighted in the forenoon. My collection, for this reason, contains plates which were exposed at every hour of the day. The picture of a fir-wood was taken at a quarter past six in the evening, and for this reason is rather wanting in detail; another with foliage was exposed at eight o'clock in the morning. But then the latter was fully exposed with a period of two minutes and a half, while the evening pictures with the fir had no less than twenty minutes given to it. Therefore the exposures, which were governed in a measure by the size of the diaphragm, lasted from two minutes to twenty in the extreme case. All the pictures I have taken are landscapes, and include tree studies, rocks &c. Some of the clichés are a little hard, but as the blacks are transparent they will print very harmoniously.

"If you will give me a little more of your time, gentlemen, I shall have much pleasure in developing in your presence, in the same way as I did on my journey, a plate which was exposed at Barbizon a week ago, with the object, indeed, of being manipulated before you this

evening. Being desirous, before everything, of suppressing all manipulations connected with photography which might be embarrassing *en voyage*, I omitted to wash my plates with alcohol before developing them, for this operation renders a second necessary—that of washing the plate again after having applied the alcohol.

"As soon as the plate is taken out of the frame, I put it into a dish, and pour upon it a solution of carbonate of ammonia, made up—

Water...	1 litre
Carbonate of ammonia	30 grammes;

to which is added—

Bromide of potassium	3 grammes.
----------------------	-----	-----	------------

"As soon as the plate has been flooded with this, and has become thoroughly moistened, I pour off the liquid into a developing cup, and add some concentrated pyrogallie acid solution in alcohol. The moistened image should become developed by degrees. To intensify, it is sufficient to renew the solution of carbonate and pyrogallie acid. If the image appears hard by reason of a lack of pose, it is well, as M. Davanne has indicated, to add a little saccharate of lime to the developer. In this way the desired value may be given to the cliché.

"The development may also be by a solution made up of—

Pyrogallie acid	4 grammes
Bromide of potassium	2 "
Water	1000 cub. cents.

"This first liquid serves to moisten the plate; by adding a little of a saturated solution of carbonate of ammonia, the cliché begins to develop. In this case intensifying with silver solution may be resorted to, and will be found to give good results.

"My plates are fixed with a solution of hyposulphite of soda.

"In conclusion, I may remark, that the interest felt in the emulsion process is proved by the attention given by photographers of late to recent improvements in this direction. The fact that the process permits us to suspend many of our old manipulations, and at the same time to work without a silver bath, is sufficient to ensure for emulsions a place in the future of photography."

IMPURITIES IN THE SILVER BATH.

SOME discussion has recently taken place among the members of the Berlin Society for the Advancement of Photography anent the impurities of the silver bath—or, rather, of nitrate of silver. It was suggested in the course of the discussion that the defects forming the subject of complaint were due to the distilled water rather than to the silver, the former, when purchased commercially, being frequently of an objectionable character, and far from pure. This reproach against the ordinary distilled water of commerce will receive support in this country, for water is often sold by chemists and druggists with us which contains a large quantity of sediment and organic matter, emanating, in all probability, from the receptacles in which the distilled water has been kept. No doubt photographers who derive their sources of supply in this way will do well to consider this element of risk in the preparation of their silver baths when the latter are out of order; but still, difficulties which arise from this cause are far more easily got over than those which arise from impurities in the nitrate of silver.

One reason why our nitrate of silver is sometimes impure is because the metallic silver employed for the preparation of the salt contains elements which are not altogether separated on the dissolution of the silver in nitric acid and the subsequent crystallization of the salt. Again, it is asserted by some photographers that the nitrate of silver is carelessly crystallized and washed, and has adhering

to it impurities from the mother liquor, and these tell us that they can never trust to the nitrate of silver they purchase, but have to go through the process of dissolving the salt and recrystallizing it again. With us, it is found that the salt usually obtained in commerce is unfit for the preparation of nitrate baths, and it is only the more expensive product—the fused or recrystallized—which is to be trusted in the making up of a silver bath.

Our Berlin friends, it seems, complain more especially of lead as an impurity in nitrate of silver, and Dr. Vogel has published some directions as to the tracing of this impurity in the silver salt. The President of the Society recommends the dissolution of one part of the silver salt in two hundred parts of water, and the adding to the clarified and filtered solution some Glauber salts solution, free from chlorine. If lead be present, a very marked turbidity is the result by the formation of sulphate of lead. Another, but less delicate test, consists in dissolving the nitrate of silver in a little water and adding ammonia to the solution. A precipitate results, which, on the addition of yet more ammonia, is dissolved again. If, however, lead is present, a turbidity will still remain, even after an excessive addition of ammonia. To separate the lead, the following plan might answer. One-tenth of the nitrate to be purified is dissolved, the silver oxide being precipitated by means of alkali. The remainder of the nitrate, dissolved in water, is boiled for half an hour with the oxide of silver, separated by filtration from the other solution, and this oxide will then, in all probability, precipitate the lead contained in the larger solution. Dr. Vogel had not, he said, practically essayed this method of operating, but it answered very well, he averred, for separating copper from silver. Lead did not, happily, interfere much with photographic operations, but in this form was to be regarded as an adulteration rather than anything else, a costly metal being mixed with one of little value.

It has been the custom in some studios to add lead to the silver bath in the form of sugar of lead or acetate of lead, for what reason is not quite clear. But to recover the silver from old baths, the solution used frequently to be treated first of all with sulphuric acid, in order to separate the lead compounds from the silver residues. The addition of sulphuric acid to the bath, under ordinary circumstances, is, however, fraught with many evil consequences. The acid will produce upon the plates innumerable pinholes, the result of sulphate of silver crystallizing out upon the collodion film. The slightest trace of acid will produce evil effects, and utensils which have previously contained it will frequently cause defects of the kind, even when the precaution has been taken to wash them with some care.

M. ROUSSELON'S PHOTO-GRAVURE PROCESS.

M. ROUSSELON, as the photographic world is well aware, has succeeded in producing some very good work by a process of photo-gravure. A portrait of M. Davanne, the Vice-President of the French Photographic Society, which was published some time ago in the *Bulletin*, was a most excellent picture, and there cannot be a doubt that to M. Rousselon belongs a great deal of credit indeed for the manner in which he has elaborated and improved the photo-gravure method, by which these fine results were obtained.

It is not, however, so certain that the principle upon which the process is based is the discovery of M. Rousselon himself. Many may think this is of little importance, since the fact remains that M. Rousselon can produce good work, while others are less competent to do so. And this, doubtless, is a good common sense view of the matter; we only wish that M. Rousselon were content to take it. Unfortunately, this is not so. In the last edition of the *Bulletin* there appears a distinct claim from M. Rousselon to have been the discoverer of a

chemical means of imparting granulation in the photo-engraved block, another French experimentalist, M. Placet, having, it seems, put himself forward as the one to whom such honour is due. Now, according to Mr. Woodbury, it is neither M. Placet nor M. Rousselon, who is the discoverer, the first having repeatedly laid claim to the invention in these columns. Mr. Woodbury has told us over and over again that the suggestion to impart grain to his photo-relief images, and thus secure prints in fatty ink from an engraved plate, came from himself, and M. Rousselon has never denied the fact; and Mr. Woodbury has further pointed out that while medal after medal has been awarded to the French experimentalist, the latter has never ventured to mention the principles upon which his photo-gravure process was based. M. Rousselon is the principal of MM. Goupil's photographic establishment at Asnières, where the Woodbury photo-relief process is so much employed; and Mr. Woodbury, it seems, supplied the latter with much information connected with applications of the process, not omitting the means of imparting to the gelatine matrix a certain grain.

We should have been well content to let the matter remain as it was, since it is very probable, indeed, that in M. Rousselon's photo-gravure process as much depends upon nicety of manipulation and upon the improvements which M. Rousselon has contributed, as upon the principles of the process. But as M. Rousselon has now come forward to claim the principle from another, we think it is high time that the matter should be clearly set out before the public. If M. Rousselon does not employ Mr. Woodbury's modification of the photo-relief process, what motive can he have for claiming to be discoverer of introducing grain by chemical means? We append M. Rousselon's letter in which he sets up this extraordinary claim.

"To the President,—In the *Bulletin de la Société Française de Photographie*, No. 5, I find a long article by M. Placet, in which he indicates the processes he has patented to obtain photo-engraved plates by means of photography. The terms of this specification are so very general that it may be said that he reserves, as being his property, all means to obtain a chemical grain, whatever the mode of operating or substances employed. I therefore address you, sir, the President, believing that it is necessary to protest against such an encroachment upon my incontestable rights in having discovered chemical means to obtain grain in engraved plates obtained by the aid of photography. This discovery has already brought me in awards from Vienna, Brussels, London, and Paris.

"Without desiring to judge or discuss the value of M. Placet's process, whose interesting work I am far from denying, it would be unjust, it seems to me, that in a few years' time, with the support of the article in the *Bulletin* in question, if it were possible for M. Placet to be in a position to claim priority of invention.

"I count, Mr. President, upon your high impartiality to allow me to make this reclamation.—Receive, &c.,

"H. ROUSSELOX."

A DANGER TO BE GUARDED AGAINST.

An experienced chemist and photographer sends the following timely hint.

"Now that so many persons are experimenting with alkaline development, a danger of fog arises from the escape into the atmosphere of ammonia vapour when such experimentation goes on in the same dark room in which the wet process with bath and iron developer is also being practised.

"In order to avoid this danger, it is imperative, before preparing and developing plates in the ordinary manner, after plates have been developed by the alkaline method, that the air of the dark room should be completely changed by ample ventilation, or neutralized by the sprinkling on the floor, &c., of acetic acid."

FRENCH CORRESPONDENCE.

HOLIDAY TIME—GOUGENHEIM'S COLLODION: FAVOURABLE REPORTS BY MM. ANDRA AND JOLIOT—SULPHATE OF COPPER IN THE DEVELOPER—DESPAQUIS' COLLOTYPE PROCESS—REASONS FOR EMPLOYING GLASS INSTEAD OF METAL.

HOLIDAYS have already commenced in the case of those whose business or connections do not keep them in Paris. The meeting of the Society on the 3rd August, which was the last of the session, was on this account not very numerously attended.

In giving an account of the former meeting, we stated that M. Gougenheim communicated the formula of a rapid collodion, and also placed in the hands of the President some samples of the material for trial by any who desired to make experiment with it. On the present occasion M. Andra gave some account of his success with the collodion, and exhibited to the members some of the clichés which he had obtained. He declared that the collodion seemed to him excellent in every respect, and he added that for his part he had never encountered a better. These were his own words.

As to the developer, which my readers will recollect contains sulphate of copper, M. Andra stated that he did not find it, so far as rapidity is concerned, possessed of any advantages. He found that he secured results quite as readily by suppressing the use of the copper in the formula indicated by M. Gougenheim. M. Andra affirmed, indeed, that the copper salt, on the contrary, acted as a restrainer or moderator, the term M. Boivin employs for the bromide in alkaline development.

Another member (M. Joliot, the successor of the famous firm of Lejeune et Levitaky) tried the collodion of M. Gougenheim, and he also reported favourably upon it. He agreed with M. Andra, that addition of sulphate of copper to the developer did not seem to have much influence upon its action. At the same time M. Joliot made the same remark with regard to the Boissonas process, of which he possesses the right to practice at Paris. In this process the same salt is set down in the development formula, but its suppression does not materially alter the results obtained.

M. Despaquis forwards me some details of his photo-mechanical process in greasy ink. This process is based upon the double exposure of the gelatine; that is to say, after the plate covered with gelatine is put under a cliché in the ordinary manner, the former is turned round and exposed to light a second time from the back, until the action of the rays have met together. A glass plate, by reason of its transparency, is specially adapted for the vehicle of the gelatine, and it is upon the latter that the printing is done, in the same way as Albert, of Munich, and others proceed. Thanks to its supple character when wet, the film of gelatine is less open to injury than even steel, and it permits of a much larger number of impressions being taken than if it were metal. Other reasons are in favour of the printing being direct from the gelatine. Gelatine will not adhere to a polished metal surface, and will adhere but slightly if it is grained. To work a grained copper plate, the same must be coated with a thin film of gelatine, so that the large transparent portions of the clichés allow the light to pass as far as the metal itself, and in this case the grain of the copper is entirely reproduced upon the image, giving the latter a very disagreeable appearance; only a limited supply of copies can be struck off in this case, and these are of a defective nature. If the film of gelatine is a thick one, the grain is less apparent, but then but a very few prints can be pulled, because of the tendency of the gelatine to swell up when moistened.

Even with the process of M. Despaquis (exposure of the film to light on both sides) it is necessary to employ polished plates. No matter how finely a glass is grained, the grain always appears upon the print in the end, and takes away from its delicacy. One other condition is indispensable to

success : it is necessary that the film of gelatine upon the glass should be of uniform thickness throughout. The manner of operating adopted by M. Despaquis is as follows:—After the gelatinized plates have been exposed to light from the back, as M. Albert, of Munich, recommends, they are placed in a perfectly horizontal position in the drying cupboard, employing a water level to ascertain if this is the case. A solution composed in the undermentioned proportions is, in the meantime, prepared, namely:—

Ordinary water	...	1000 cubic centimetres
Strong gelatine	...	25 to 30 grammes
Bichromate of ammonia	...	6 to 7 „

The bichromate is dissolved in one hundred cubic centimetres of the water, and then the remaining nine hundred are added in which the gelatine has been previously dissolved. The filtration of the liquid is conducted by means of paper or fine linen. The drying chamber is warmed so that the gelatine surface should not set before it has become perfectly level, a result which might happen if the chamber were cold. Then the solution is poured upon the plates in such a way that the superfluous liquid escapes at the margins, and leaves a perfectly uniform film. So that the fluid may run the more uniformly, it is well to wet the margins of the plate by passing the finger along them. When this second film has dried, you may then proceed without fear to expose the plate a second time under the cliché. The process, in a word, resembles very much that of M. Albert, of Munich, but there are some important differences of detail which are said to have much influence upon the result.

ERNEST LACAN.

PHOTOGRAPHY IN AMERICA.

BY NORMAN MAY.*

As salaries are what the intending emigrant generally thinks of most, I will give a few cases that came under my own immediate observation, and which I can guarantee as being absolutely correct. I have not heard so much about the prospects in America lately, but three or four years ago I know there was an idea that exorbitant salaries were paid, especially to retouchers. I knew a retoucher in the West of England who at that time was getting £4 a week, and yet was dissatisfied, as he had been assured he could get at least thirty-five dollars, or about £7 a week, in New York, or any large city in the Union; but at that very time a photographer in Detroit, whose pictures were universally praised for the splendid retouching, was only paying two dollars a day, or about forty-eight shillings a week, to the retoucher, who was quite satisfied with his salary. Very high-flown accounts are often sent home from America, generally to relieve friends from anxiety. I knew of a young fellow, then in New York, who wrote to his parents in England, and, giving his address as Ward's Island, where there is a refuge for destitute emigrants, he gave them to understand that he was a clerk in the establishment, not liking to worry them by saying he was an inmate; but he was, though, and he stayed there some months, during which time he used to write home telling them he was very comfortable, and getting on well, but was afraid it was not a very permanent situation. That kind of thing is very pardonable in such cases, but still it is apt to mislead people who think of emigrating, and I know the accounts sent home sometimes are, to put it mildly, a little exaggerated. We will just suppose this retoucher could have got £7 a week in New York, how much better off would he be than on £4 in England? The necessities of life are much dearer, and, taking it altogether, he would find he had made a mistake, even at that salary. Twelve dollars are thought a very fair salary; there may be instances of more being paid, but still the average would certainly not be above that. A Canadian operator, whom I knew well, had twelve dollars a week,

and that, also, was thought first class pay there. The same man would have no difficulty in getting £3 or £4 in England. In addition to being an excellent operator, no one, I know, could equal him in suavity of manner and the tact with which he understood and managed his sitters. His knowledge of human nature was great, and had been improved by travelling, and customers went away pleased with him and themselves, feeling sure they would like their pictures. Such operators are by no means common anywhere.

I knew other operators in Canada who didn't get over six or eight dollars a week; average sort of men; they were such as would get thirty-five shillings or £2 in England. One operator I knew was paid seven dollars a week, but his employer not doing enough business, he obtained a situation elsewhere at five dollars. He was a very steady married man, and had been in business for himself. A printer's pay would be five or six dollars, up to nine or ten dollars for a first class one. Lads of seventeen or eighteen got three and four dollars a week as printers. I knew a very good printer, who was also a fair operator; I am not quite sure what his salary was, but the last I saw of him was in Detroit, engaged in the intellectual employment of varnishing bedsteads for a furniture manufacturer. Nine dollars, or about thirty-five shillings, he got for that; but it was evidently an improvement on photography as far as salaries were concerned.

There was a good general assistant, a man about fifty, who had been in business at Cape Colony; he was getting six dollars in Canada, which he said suffered in comparison with the Cape. A decent colourist got eight dollars; but even that didn't last through the winter, and he was obliged to seek fresh fields and pastures new.

All these mentioned were well spoken, intelligent fellows, such as would find ready employment in England at good pay. I've noticed lately several advertisements from operators and retouchers who have just returned from America, so they evidently didn't find it up to their expectations. Colourists are rather at a discount. I was shown some cabinets very nicely tinted, in Chicago, for which the munificent sum of twenty-five cents, or one shilling, was paid. A Canadian photographer who visited me a short time since expressed himself greatly pleased with the state of photography in England, and thought seriously of selling his business and settling in the "old country," not only on account of the improved prospect for making money, but for the better education of his children. He is an extremely well informed man, and has ample opportunity of judging the merits and demerits of the respective countries.

In winter the photographer has many competent assistants who are willing to work for their board. In all branches of photography the competition seems so great that wages are kept very low indeed in proportion to the mechanical businesses, and compared with England, taking into consideration the purchasing power of money in the two countries.

I am afraid that these remarks will be thought discouraging to the intending emigrant, but I write only of cases that came under my own observation, and, perhaps, others can give a more flattering account.

(To be continued.)

ON THE DEPTH OF PRINTS AND INTENSITY OF NEGATIVES.

BY CAPTAIN ABNEY, R.E., F.R.S.*

IN continuation of the last communication I propose to show the action of the spectrum on albuminate of silver and silver chloride. In order to obtain the prints, a spectrum was formed by sending a slice of white light, after passing through a collimating lens, through one flint glass

prism. The light was received on a lens of six feet focus, and a bright spectrum thrown at that distance from it on the sensitive sorts under examination. As it would have been nearly impossible to measure the depth of printing had the slit been so narrowed that all the fine lines had been shown, the slit was opened to such a point that only the principal lines were visible, and these were left to serve as an index to the position of the different intensities. A sensitive plate was finally exposed with a very fine slit, all the apparatus remaining untouched, and a print taken from it in order to fix more definitely the position of the intermediate intensities. The accompanying diagram gives the results obtained.

Fig. 11.

At first sight it seems to be merely a record of black and white, and not of sensitiveness. If, however, it is translated into intensity of actinic power the significance is at once seen. This has been done in the next diagram.

Fig. 12.

The sensitiveness of the chloride of silver and the albuminate both commence at the same ray of the spectrum. The point of maximum intensity of the former is at G, and of the latter about F in the solar spectrum. Now this must not be received as an absolute result of the necessary sensitiveness of these salts to the various coloured rays, but simply the sensitiveness for *printing purposes*.

This is no unnecessary distinction, for with development before the colour of the compound has changed it would be found that the points of maximum sensitiveness would be altered. The reason is apparent. The silver albuminate and chloride both have distinctive colours where acted upon by light, as already pointed out, and the colour of the former is such that for equal thicknesses more of the blue and violet are cut off than in the latter; hence the greater comparative depth of black produced towards the green in the former than in the latter.

I might have exemplified this at a greater length had I given diagrams showing the difference that occurs in the points of maximum intensity produced by placing in front of the slit of the spectroscopes in the case of albuminate of silver a film of darkened albuminate, and in the case of silver chloride a plate covered with darkened chloride. It would have been noticed that whilst the

point of maximum intensity in the latter remained nearly in the same position as it does at present, that that of the former shifted further towards the green. It may be objected that the films of albuminate and chloride exposed to the spectrum are thin, and cannot, therefore, have appreciable effect. The result of this last experiment proves that it has, as might also be surmised by the mere fact that blackening of a film must alter the conditions of light acting on the sensitive surface at any instant; and, again, it must be borne in mind that thinness of a film is only a relative expression. Thus a film of silver or gold which is almost too thin to measure will cut off nearly all light, and, therefore, in this respect, may be considered a very thick film. In reference to this subject it may not be uninteresting to remark that the late Sir John Herschel and Mr. R. Hunt carried out a great many experiments on the sensitiveness of various salts, the rays of the spectrum to which they were sensitive, and points of maximum sensibility being determined by them. In those cases where the results were arrived at by exposing the salts to the spectrum sufficiently long to print, a correction might have to be applied dependent on the absorption produced by the colouration.

It is scarcely needful to make any further comment on the lesson to be learnt from this portion of the subject, except that it still further shows the modification that can be made in a print by altering the proportion of albumen to chloride in albumenized paper.

For curiosity sake, I have taken two silver prints, one of rich brown tone, and the other of a black tone, and compared the deepest shades and highest lights with the standard shades. The following are the results:—

	Blue-black Print.	Brown Print.
Highest light	9.3	9.1
Medium light	7.0	6.6
Medium shadow	2.2	2.8
Deepest shadow	.5	.8

Proceedings of Societies.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

On Thursday, August 2nd, the Board of Management of the above Association met.

The minutes of previous meeting having been read and confirmed, Mr. James Henderson was elected an ordinary member of the Association.

A new edition of the rules having been printed, it was decided to send them post free for six stamps (see advt). Several alterations having taken place, it is considered advisable for all members to possess the latest edition. All information concerning the Association will be found in this book.

The next meeting will take place on Thursday, September 6th.

FRENCH PHOTOGRAPHIC SOCIETY.

A MEETING of the Society was held on the 6th inst., M. DAVANNE in the chair.

A letter from the Minister of Public Instruction was read, stating that he would be glad to help the Society as far as possible in respect to the improving of photographic apparatus for travelling purposes.

The Commission charged to examine M. Chardon's emulsion process stated that, with a view to ascertain the keeping qualities of the plates, a case had been forwarded to Shanghai, containing emulsion and prepared plates, some of which had been exposed. On the return of the box from China in four or five months an examination will be made and report furnished by MM. Andra, Chardon, and Davanne.

M. ROUSSELOU addressed to the Society a note claiming for himself the honour of priority in inventing a means for securing grain in photogravure which has been claimed by M. Placet (see page 379).

M. TURPIN exhibited to the Society several compounds of rubber, among which were an india-rubber parchment and a material termed vegetable ivory.

M. WEITENBERG (of Marburg, recommendation to employ

finely ground resin for retouching was brought before the Society.

M. LOEFFER, an American gentleman, having stated that the time necessary for printing a carbon print is the same exactly as that taken to produce a silver print (before toning and fixing), and that, therefore, a cliché with silver paper might well serve as a photometer, MM. Liebert and Franck de Villecholle remarked that such is far from being the case, since carbon tissue is much more rapid to print than albumenized paper, and, moreover, its rapidity varies with its preparation. A photometer is, therefore, necessary to measure the sensitiveness of the preparation.

The SECRETARY acknowledged from Dr. Van Monckhoven a pamphlet on the reproduction by means of photography of the ultra-violet spectrum of gases, from Dr. Liesegang's *der Kohle Druck*.

M. TRUAN, of Gijon (Spain), presented the Society with fine impressions in permanent pigments by a simplified method of printing.

M. MERCIER exhibited an instrument for adjustment to the camera, which had for its object to secure images of coloured subjects with their relative degrees of light and shade.

M. MAGNY exhibited a series of fine pictures secured with plates prepared by M. Chardon's emulsion process.

M. SCHAEFFNER showed samples of photo-lithographic paper prepared by M. Husnik, of Prague, and explained the manner in which it was used.

M. BRAUN passed round a fine collection of prints, being reproductions of the principal paintings of the *Salon* of 1877.

M. GOUGHENHEIM placed at the disposal of the Society some samples of rapid collodion, of which he gave the composition as under:—

Ether	585 grammes
Alcohol at 40°	465 "
Pyroxyline	10 "
Double iodide of potassium and cadmium	5 "
Iodide of ammonium	4 "
Iodide of cadmium	2.50 "
Bromide of cadmium	3 "

M. BARDY gave an account of his experiments on the employment of artificial colouring matters as anti-photogenic agents; also some details on the preparation of emulsions.

GENERAL WINBERG, Director of the State Paper Department in Russia, forwarded some specimens of photo-gravure intended to serve as models in schools of design.

M. BALAGUY presented to the Society a number of clichés of large dimensions, 27 by 33 centimetres, obtained by the emulsion process. M. Balaguy said:—The emulsion I employed was made in the same way as other emulsions, although I was not, perhaps, so careful in following the formulæ as I might have been. I always put a great excess of silver in my emulsion. This silver, or rather nitrate of silver, remaining free, was of course washed out when the emulsion was subjected to the washing process. I believe this excess of silver gives my emulsion a matt surface, while M. Chardon prefers to have one with a brilliant surface. In other respects my emulsion has nothing remarkable about it. The development of the plates was similar to that usually had recourse to.

The proceedings then terminated.

PHOTOGRAPHIC SECTION OF THE AMERICAN INSTITUTE.

A MEETING of this Society was held on June 5th, President H. J. NEWTON in the chair.

The minutes of the last meeting were read and approved.

A communication was read from the Glasgow Photographic Association, requesting the Section to use its influence in opposing the extension of the patent for Swan's carbon printing process, which patent was to expire in February, 1878.

The PRESIDENT remarked that in America they were not so much interested in the Swan process as they were in Europe. He did not know of anyone using that system to any great extent, and it was therefore doubtful whether an application would be made for its extension. Perhaps the best way would be to appoint a committee to take the subject of the letter into consideration.

On motion, Messrs. Duchochois, Mason, and Bierstadt were appointed a committee for that purpose.

Mr. DUCHOCHOIS said that as one of the committee on experiments he would state that he found a solution of one per cent. of alum would prevent bubbles or blistering in prints. He used double albumenized paper.

The PRESIDENT remarked that he tried alum some time since, and observed that it impaired the white parts of the print. He found a few drops of ammonia in the fixing solution to answer better than the alum.

Mr. LAUDY exhibited negatives and positives of the same pictures, and views taken by the usual bath process, also duplicates by Newton's emulsion, which were carefully examined and duly criticised.

On motion of Mr. DUCHOCHOIS, M. le Comte de Damsaux, a member of the Belgian Photographic Society, was elected a corresponding member of the Section, and the Secretary was instructed to notify Mr. Damsaux of the same.

On motion of Mr. GARDNER, a committee consisting of Messrs. Gardner, Mason, and Chapman were appointed to procure more commodious rooms for the meetings of the Section in the Fall.

An exhibition of slides was then given with Mr. Wilson's stereopticon, Messrs. Laudy, Newton, and Chapman showing some very fine views made by them. Mr. Wilson also exhibited several beautiful coloured slides.

On motion of Mr. CHAPMAN, the minutes of the meeting were to be placed in charge of the clerk of the Institute for thirty days, so that the members of the Section could examine and correct them if necessary, as the usual summer recess was about to be taken, and the publication of the proceedings might be desirable before the first Fall meeting.

The Section then adjourned to the first Tuesday in September.

Talk in the Studio.

THE FORTHCOMING EXHIBITION.—We have reason to hope, from what we hear, that the next Exhibition of the Photographic Society will be a good one. Some who have not contributed for years will send this year. Mr. H. P. Robinson, who has not exhibited now for four years, will again contribute one of the fine compositions which have made his work famous. The subject is entitled "After the Day's Work is Done": a cottage interior in the evening tide, with an elderly labourer reading the big Bible, whilst his wife listens. It is a noble composition, singularly successful in rendering the difficult light and shade of a cottage interior lighted by one small window.

WHAT ARE THE ART RIGHTS OF PHOTOGRAPHERS?—The Philadelphia *Public Ledger*, referring to the recent copying of one of Mr. Robinson's photographs, says the rights of photographers constitute "a question not yet specifically settled either in law or in the comity of the great fraternity of art, some even being disposed to deny that photography is an art, or that its products are art works. A sharp issue under this question has just been raised in England. An artist, a painter, recently exhibited in the Dudley Gallery, where 'copies' are not admitted, a copy of a photograph of the sea by Mr. H. P. Robinson, of Tunbridge Wells, who is also a painter as well as photographer. Mr. Robinson demanded that he should be credited with having made the original picture, and there has been considerable correspondence between the two artists and the committee of the Gallery on the subject. Mr. Robinson claims that the composition, lighting, and sentiment of the picture are his work, although he used a chemical process instead of his hands to fix the scene on paper, and he presents a knotty point for the committee when he suggests to them that if he had copied his photograph in oil and sent the picture to them they would have had to decide whether Mr. Macbeth's copy or his own was the 'original.' He thinks that there can be no question that the photograph is the original, and that both the paintings should be classed as copies. But if the photograph is an 'art-work,' as this would imply, artists who copy photographs should give credit to the photographers whose works they copy, just as the photographers now give credit to painters from whom they copy. There can be no doubt that a photographer may produce a picture of artistic worth in composition, lighting, sentiment, &c. (albeit he seldom does so), and the work of fixing it on paper by the aid of the camera is no more 'mechanical' than is the manual work of drawing and painting as done by most artists. It will be a safe thing to admit photographers to the fraternity of true artists whenever their works show them to be artists, for this course will not unduly swell the ranks of 'the heaven-born,' and yet will set before the working photographer a goal to stimulate his ambition."

YELLOW LIGHT.—Dr. Robert Charles Croft (204, Camden Road, N.W.) writes:—"The letters upon yellow light which

have appeared in the *Daily News* seem to have excited so much attention that I will ask you to be good enough to allow me to say a word or two more. Light transmitted through a yellow medium loses its chemical power. To this fact we are indebted for all the wonderful results in photography, since, when the window is covered by a yellow blind, the most delicate chemical operations may be carried on without being affected by the light so filtered. That yellow light has a considerable influence in abating the force and in reducing the irritation in small-pox I have had occasion to know. May it not have a similar effect in allaying the suffering caused by inflamed eyes? I saw at the sea-side yesterday some young ladies with delicate skins who were suffering greatly from being severely sunburnt, and I have no doubt that at this season of the year many persons suffer in a similar manner much pain. May I suggest that all this may be done away with by wearing yellow gauze instead of brown or green veils, and that yellow spectacles are far more likely to mitigate the glare of light than green or blue ones, especially the latter, which intensify and increase the actinic or chemical powers of light to a great extent? These matters are worth noting. Surely the worthy Doctor is in error in supposing that because yellow light is without chemical action, its glare will not be offensive to tender eyes!—Ed. P.N.

To Correspondents.

AN AMATEUR.—We have not heard of any similar defect resulting from adding nitrate of baryta to the bath. As you have added more than has generally been found necessary, possibly the minute irregular holes may be due to that. Half the quantity would have been sufficient. At present, the use of the baryta salt is based rather upon observation of its practical effect than upon any theoretical basis: its operation under different conditions will require continued observation and experiment to determine results with certainty and accuracy. When first used to get rid of pinholes, it was on the theory that the cause of these pinholes was the presence of sulphate of silver: but as it seems to prevent pinholes in many cases where there is no reason to apprehend the presence of sulphate of silver, its precise action remains at present unknown. A portion of the baryta may be removed by precipitation if you add a few drops of sulphuric acid to the bath, and filter out the sulphate of baryta thrown down.

A. CONSTANT READER.—It is difficult, perhaps impossible, to produce as good a portrait by means of artificial light as by daylight, but a pretty good portrait may be secured. 2. The magnesium light is the best—indeed, the only—really available artificial light for the purpose. 3. Details of cost of apparatus and working can be obtained by writing to Mr. Solomon, Red Lion Square, who supplies the lamp and the magnesium ribbon.

A. C. DOWN.—Your translation of the proportions is sufficiently accurate. We have never used this precise developer, and cannot with certainty say how it will work. We have employed tartaric acid, and did not like it, as we found it retarded development, and gave a thin blue image. We prefer acetic acid. *b.* Bichloride of mercury is used for intensifying in various ways. If a five-grain solution of the mercury salt be applied to a fixed and washed negative for a short time, until the surface colour is of a uniform dark grey, the negative will be found to have gained a little in intensity. If it be washed well, and then a one-grain solution of iodide of potassium applied, the negative will acquire a light olive tint, which is very non-actinic, and considerable intensity will have been gained. If, instead of the iodide, a very weak solution of ammonia or of hypo be applied, the negative will become black. There are various other modes of using the mercury salt, which have been described in our *YEAR-BOOKS*, but we do not, as a rule, recommend these intensifiers, as the negatives are apt to change afterwards. *c.* We have published in former volumes all the details to which you refer. You will see that we cannot with propriety often repeat such things, in justice to earlier subscribers who preserve their volumes. If you wish for details regarding any particular chemical we can give you brief details. *d.* It is desirable that the dark slide should be sufficiently large for each plate to be placed in and taken out easily; but it is unpardonable that dry plates should be so much below size as to drop through the slide. In such a case the plate should be made good by the vendor.

B. HARLEY.—You omit a most important element in the case. You do not state the size required in the photograph of the monument. The performance of the lens, as you describe it, does not seem very good; but it may be much better when used with a small stop, which is desirable when photographing the monument. Of the lenses you name, No. 1 is preferable.

J. H. R.—The landscapes are exceedingly good and interesting. We are glad to see one of the negatives; the technical qualities and the colour are very excellent.

B. R.—The alum bath for preventing blisters has been found successful in the United States. It is described as follows:—"A bath of alum (consisting of one part of pulverised alum to sixty parts of common water), to be used immediately after the toning bath, and letting the sheets soak five to ten minutes. Afterwards one proceeds in the accustomed way to fixing. In using this remedy, care should be taken that the acidity of the alum should be corrected before the immersion of the prints in the hypo bath. It is possible that the alkaline condition of the prints upon emerging from the toning bath may be sufficient to neutralize entirely the acid reaction of the alum. This can easily be tested."

ECONOMIST.—Much depends on the number of negative films. Silver may undoubtedly be recovered, but whether remuneratively or not, we cannot say. It has been done in America. At a recent meeting of the Philadelphia Society Mr. Clemons said that in working over some silver residues a short time since he had extracted 2 ounces, 2 drachms, and 24 grains of metallic silver from 1000 old negatives 8½ by 6½. Plates that had been treated with sulphide of potassium did not yield as much silver as those simply finished without strengthening.

AN AMATEUR.—Something depends on circumstances; but, as a rule, a negative does not require more than one-fourth or one-third more exposure than a collodion positive.

AMATEUR.—Your gum-gallic plates developing on the merely placing in water to soak, prior to legitimate development, is not a very unusual thing with very fully exposed dry plates of that kind. Yours had doubtless received a full measure of exposure, and gallic acid, being a developing agent, brought out the image as soon as the water made it into solution.

H. F. R.—The stippling of the flesh is very neatly done; but the colour is a little too bright and raw. The backgrounds are a little too rough.

NORMAN MAY.—Thanks. The papers are very interesting and useful.

WELLESLEY TURNER.—Your revised list of prices for carbon enlargements received. Thanks.

Several Correspondents in our next.

METEOROLOGICAL REPORT FOR JUNE.

BY WILLIAM HENRY WATSON, F.C.S., F.M.S.

Observations taken at Braystones, near Whitehaven,
36 feet above sea-level.

Date.	BAROMETRIC PRESSURE.			TEMPERATURE IN THE SHADE.			REMARKS.
	Morning.	Noon.	Night.	Morning.	Noon.	Night.	
1	29.18	29.20	29.27	60°	61°	63°	Heavy showers a.m. and p.m. Very strong wind
2	29.32	29.37	29.46	54	58	53	Rain this evening. Gloomy all day
3	29.50	29.48	29.45	56	63	55	Fair, generally sunny
4	29.50	29.52	29.48	59	63	66	Rain this evening
5	29.40	29.58	29.75	66	59	55	Rain, with strong wind, at night
6	29.70	29.56	29.53	55.5	58	50	Rain up to six p.m.
7	29.56	29.69	29.00	54	58	52	Fair and sunny
8	29.91	29.82	29.70	58	56.5	55	Rain afternoon and night
9	29.76	29.80	29.80	58.5	—	55	Fair, generally sunny
10	29.80	29.80	29.86	58	59.5	56	Rain this morning. Generally gloomy
11	—	29.96	29.90	58	65	54.5	Fair and sunny
12	29.82	—	29.87	58	68	57	Fair, generally sunny
13	—	29.90	29.95	62	65	59	Fair, very sunny
14	—	30.00	30.02	59	66	58	Fair and sunny
15	30.03	30.08	30.06	62	68	60	Fair and sunny. Very clear
16	30.08	30.05	30.02	61	71.5	61.5	Fair and sunny. Very clear
17	30.00	—	30.00	66	75	65.5	Fair and sunny
18	29.99	29.99	29.98	72	78	70	Fair and sunny
19	30.01	30.01	29.99	71	76	69	Fair, generally cloudy
20	29.93	29.95	28.80	73	77	65	Fair, generally cloudy
21	29.82	29.97	29.61	70	78.5	68.5	Fair, generally cloudy
22	29.41	29.57	29.55	67	63	55	Rain a.m. and p.m. Rather windy at night
23	29.50	—	29.76	60	—	51	Fair and sunny
24	—	29.98	29.97	56	59.5	54	Fair and sunny

During the warm weather, from the 16th to the 21st, the temperature at three o'clock in the afternoon was several days up to 84°.

The Photographic News, August 17, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO. A MAGAZINE ILLUSTRATED BY PHOTOGRAPHY—ON POSING IN PORTRAITURE.

A Magazine Illustrated by Photography.—Photography has made one more step in advance in the matter of book-illustration. For the first time one of our magazines appears with a photographic illustration, and there cannot be a doubt but that it will be the forerunner of many such pictures. Such circumstance brings us still nearer the goal we are approaching, when photographs will compete with woodcuts and engravings in our literature. The particular case we refer to is the *Dublin University Magazine*, the distinguishing feature of which is a portrait of Tom Taylor, the editor of *Punch* and well-known playwright. The portrait is one taken by Messrs. Window and Grove, and is produced by the Woodbury photo-relief process. Strange to say, this is the only process, seemingly, which is being worked by photo-mechanical printers, and Lichtdruck or Collotype printing would seem for the moment to be in abeyance. It is difficult to understand why this should be. That there are unlimited demands for mechanical printing now-a-days is tolerably obvious, and the number of Woodbury pictures struck off in London, Paris, and elsewhere must be exceedingly great at the present moment. But one sees no Collotype impressions about. They can be produced very successfully, as everybody knows who has witnessed the proofs that have come to us from Germany from time to time, while in our own YEAR-BOOK we have shown that the art is practised with no little success in this country. Collotype prints have many advantages to recommend them, not the least being that they are produced by a fatty ink, and are as permanent as ordinary print and paper; they require no mounting, and lie as flat and even as any printed matter with which they may be bound together. We have Collotype prints in our possession, both portraits and landscapes, received four or five years ago, which would satisfy the most fastidious of publishers, and yet to-day we seem just as far off as ever of putting forward a well-illustrated book with pictures by the Collotype method. The reason, we fear, is to be found in the fact that the Collotype process cannot always be worked with that degree of perfection and certainty so necessary in commercial matters. Good prints are produced every day, so good that, as we have said, any publisher would be glad to accept them; but we have not, apparently, arrived at a sure and uniform mode of proceeding, which can only be secured when the production of the negative, of the block, and of the print, are sufficiently under the control of one skilled and experienced in the particular conditions to be fulfilled. In printing, a most delicate operation in Collotype work, not only is a skilled printer required, but he must be an experienced Collotype printer. And where is he to be obtained? There is no school of instruction open to him, and consequently time must elapse for men who are, perhaps, skilled in the kindred art of lithographic printing to become experienced in pulling prints, not from a hard, unyielding surface, but from a comparatively soft and spongy one. We say that we must wait until lithographic printers learn Collotype work; and yet we are not so sure whether they would, after all, be the most likely people to employ, since they would have much to learn and more to unlearn, and a man already thoroughly versed in one art is usually not very ready to learn another. He is conservative, and likely to stick to his old ways, which have hitherto given him good results. And the printing difficulty is, as we have said, only one to be got over. The production of a block, soft and delicate, with all the half tones of the cliché, and yet possessing vigour in the blacks, is not so easily done as many think who read the details of the Lichtdruck process which have appeared in these columns and elsewhere; for while at times success may crown one's efforts, this is not always to be obtained at will. There is,

in a word, much still to be done in Collotype printing before it can be said to be outside the domain of experiment.

On Posing in Portraiture.—The time, fortunately, has gone by when the photographer was worried by the visits of "friends" to his studio, who accompanied the model, as they modestly explained, in order to pose him or her. In the early days of photography such occurrences were very frequent, and sitters would come accompanied by a brother or sister, uncle or aunt, who had an uncommonly fine taste in all art matters, and who had, therefore, consented, for the nonce, so far to sacrifice dignity as to enter the studio of a photographer, and show the latter how to pose properly. We should like to hear what Mr. H. P. Robinson, of Tunbridge Wells, or Mr. Valentine Blanchard, would say now-a-days to any such individual who desired to teach them something of their art. We once met a painter in the lobby of a dining room, who innocently thought to ingratiate himself with some noted photographer present, by remarking to us, *sotto voce*: "Ah! I thought that was Mr. Camera; I used to know him some time ago, and helped him a good deal with his work. I don't mean, of course, the photographic part of it, for I don't profess to know anything of that, but the art aspect of the matter. He liked me to come and pose his sitters for him." Luckily, the Mr. Camera was at some little distance, and did not hear the remark, otherwise I fear an explosion of some force would have followed. But the idea certainly is, with many painters and draughtsmen, still, that the photographer is incapable of posing well, and that this part of the duty is done quite haphazard, the result being good if the sitter himself has posed with a *savoir faire*, and the reverse if such is not the case. The photographer, in any case, has nothing to do with the result. But it by no means follows—and this, people are very apt to forget, whether they are artists or not—that, when you assume an easy attitude, the same looks easy and graceful. There never were, for instance, more born gentlemen on our stage than at the present moment, most of them possessed with the idea that they can fulfil the rôle of *jeune premier*. And yet these very men do not seem to behave as gentlemen on the stage. It is one thing to be easy and unconstrained, and another thing to appear so without offending good taste. This only comes with experience, and no young man, however well he comports himself in a drawing-room, could hope to place before an audience such an artistic picture as, for instance, Mr. Charles Matthews's finished acting represents. In the same way, sitting down easily in a low chair before the camera does not, perforce, produce an easy pose. An experienced photographer, however, knows what will, and he sometimes makes his sitters assume what they imagine must be a very stiff attitude, in order to produce the wished-for effect. And, singularly enough, painters seem quite as liable to err in this simple matter as other people. The other day we were looking over a collection of cabinet pictures taken for the most part with considerable taste and skill by a gentleman amateur. A lady at work before a sewing-machine was admirably contrived, the machine and work being carefully subdued, so as not to obtrude and take away from the portrait itself; another more difficult subject still, a cricketer, all in white, was also capitally rendered; but a third portrait was, on the other hand, terribly marred by the centre of the picture being taken up by two square slabs of considerable dimensions, the one representing the sketching book, and the other the palette of an artist, whose face occupied the left hand top corner of the photograph. He was posed, paint brush in hand, in a low chair in a most painful and constrained attitude, apparently, in which it would have been impossible for him to move, except by spasmodic action. And this pose was not that of the photographer, but of the painter himself, who, no doubt, would have resented any interference on the part of an amateur. "Here I am: I am a painter, do you see. You observe my palette, and brush, and picture, and this is how I do them." Thus spoke the picture as plainly as could be.

CLEANING AND RESTORATION OF OIL PAINTINGS.*

Cleaning Oil Paintings.—It is oftentimes the case that both frames and oil paintings are left with the gilder to renovate, and it is highly important that he should be informed as to the best methods in use for cleaning, remounting, varnishing, &c., and also to know some of the best receipts used in the various processes. It may be as well to caution the inexperienced not to attempt too much, as an error in judgment, or careless manipulation, may entirely ruin a valuable picture; and those who wish to undertake the restoration of oil paintings must, in the first place, be careful, and then try some of the most simple processes, before trying those which would even tax the skill of the experienced. The cleaning and restoration of paintings is usually paid for most liberally, and to the man of business this chapter will be worth gold and silver, while the amateur who wishes to try his hand on one of his own pictures will be delighted with his success, if he possess the skill and judgment to follow the instructions laid down. Oil paintings come to hand for restoration in almost every state of decay; and where a valuable work of art has been neglected, with the canvas rotten, or worm-eaten, or where the body of paint has parted from the canvas, or where the picture is cracked badly, and pieces of the picture fall away, it requires thought, judgment, and a careful and skilful man to treat these works of art so that succeeding generations may be delighted with their beauty.

Cleaning oil paintings is a most important operation, and one that requires great judgment as well as skill—judgment to decide what treatment is really required for the state of the picture, and skill to successfully carry out the necessary work. The condition in which pictures are found is so various, and produced by so many different causes, added to which, the various grounds on which colours of various chemical proportions are placed, justifies our opening remarks. A few cautions may be acceptable, as no positive rules can be laid down for the successful treatment of every subject. Care should be used not to saturate the face or back of the picture with water, as the absorbent nature of many of the old pictures would completely ruin them. Damp will make canvas rotten, and it is difficult oftentimes to get the damp out of a painting when once it has been saturated. A soft sponge with the water squeezed out of it, or a soft leather well wrung out, should be the extent of water application, and the picture never flooded. If damp is applied to the back of an old canvas, it is likely the picture will blister, or come up from the base. Before commencing it is almost needless to say the dust and dirt on the surface should be removed carefully by sponging.

In cleaning paintings, our efforts must be directed to the removal of three things:—Stains or discolouration, dirt, and varnish. A remedy for the first is ox-gall, applied with a soft brush till the stains disappear, and sponged clean.

The removal of varnish oftentimes occasions great trouble, especially when it is old and hard. If it is mastic, and has not been laid on many years, it can be removed by the friction of the finger; but a solvent must be employed to remove old hard varnish, and requires careful manipulation. The picture must be laid on a flat smooth surface, and having made up a wad of cotton wool, give it a dressing with the following mixture:—

Wood naphtha	3 ounces
Spirits of salts	1 ounce
Lined oil	½ pint

Commence with a circular motion of the hand; after a time, the picture, if very obscure, will gradually come out in all its details, but care must be taken that the rubbing is not carried too far, or the picture will suffer. Each time the mixture is applied to the rubber, it should be well shaken, and a new and clean place of the rubber chosen. The

lightest parts of a subject should be chosen to commence upon, so that it can be then seen how the work is progressing. The look of the painting and the colour of the rubber will tell the practised eye when to stop the action of the solvent, and it should be wiped over with spirits of turpentine. The above receipt will work much quicker where the varnish has not been laid on for any length of time. A stronger solvent for varnish may be required, and any of the following may be used, but only in practised hands, as they are known to be powerful agents in their work:—Spirits of wine, oil of tartar, pure alcohol, liquor ammonia fortis, soda ether, naphtha, and oil of spike lavender. In using any of the above, the operator should know what antidote to apply in case their action is too rapid. Copal is the hardest varnish and will require some of the more powerful.

It is scarcely necessary to mention here, that where a picture has not been varnished, no solvent must be applied to remove any dirt, &c., but a leather wrung out with water and a little of the finest whitening, to produce a little friction, will most likely clean the surface.

The removal of varnish by friction is a common method and is done by rubbing the face of the painting with the first and second fingers of the right hand, previously dipped in powdered resin. The varnish, if it is mastic, will soon give way, and come off in fine powder. The surface of the painting must be wiped frequently to see how the work proceeds or it may be very much damaged.

If pictures have received damage, and present an uneven surface, and require the restoration of colour, all indentations on which it is desired to apply colour should be stopped up with either the stopping or the compo used by gilders. The first is parchment size and whitening, mixed into a thick paste, and the second is glue and whitening, the receipts for which can be seen in another part of this volume. Either of these must be carefully laid on with a small palette knife or modeller, and well smoothed down. The surface of the picture should then be cleaned over with turpentine.

The restoration of colour in old pictures is difficult, and, in many, the colours never can be restored to their original beauty. Where pictures have been hung in dark corners, and have scarcely seen daylight, they would be greatly benefited by being placed in a strong light for a length of time. We have recently found this to be very beneficial to a pair of portraits looking very much as if the artist had painted a post mortem representation, which came out in the course of nine or ten weeks in blooming health. The effect of a strong light on paintings, in the restoration of colour, is sometimes wonderful.

Where a picture has been restored, before varnishing, it would be advisable to put on a layer of weak isinglass, which is transparent, and would be a slight interposing medium. This will prevent the new paint cracking, if varnished before it is sufficiently hard.

Picture Restoration.—In the course of the correspondence on the genuineness and condition of some of the paintings in the National Gallery, Mr. J. C. Robinson has furnished the following particulars of the theory and practice of picture restoration:—

"The thick, solid painting of 'oil-pictures' is generally executed with colours in which the oil greatly predominates, but the more delicate and transparent tints and minor details are executed with varnished colours tempered with a minimum quantity of oil.

"Now, the oil vehicle is the hardest, toughest, and most durable; the varnish medium, on the other hand, is much more tender and evanescent. Moreover, the transparent tints executed with it are very thinly applied, most frequently on the surface of the picture, as more transparent washes, technically called 'glazing.' In the pictures of some schools and particular masters the place which these 'glazings,' &c., occupy in the general pictorial scheme or 'technique' is all important. For instance, in the works of the Venetian masters, commencing with Titian, of whom many of the Dutch seventeenth century painters, &

Claude Lorraine, and, above all, of our own Sir Joshua Reynolds, the entire lustre, depth, and vivacity of colour—all the most fascinating qualities, in fact—are due to the infinitely various and skilful manner in which the final or superficial paintings, 'glazing,' and 'tonings,' are executed in these rich, transparent varnish colours.

"But from the beginning to the end of the 'building up,' if I may so express it, of every oil-picture, portions of the work are alternately executed in the harder oil vehicles and in the tender and more perishable transparent varnish colours. These pictures are never homogeneous in their composition—that is, they can never oppose exactly the same amount of resistance to deteriorating agencies in all portions of their surface or substance.

"Pictures are, unfortunately, habitually subject to be cleaned—i.e., washed over for various purposes with fluid solvents, such as turpentine and spirits of wine. The latter fluid, if applied in sufficient quantity and strength, and for a long enough period, to the surface of the picture, would entirely dissolve it, and remove every vestige of the paint from the canvas or panel; but this particular solvent acts irregularly and unequally—very slowly upon the portion of a picture painted with the solid oleaginous vehicle, but rapidly on the transparent resinous tints; in other words, the alcohol rapidly dissolves the gum resins of which the varnish colours are mainly composed, while, at the same time, it leaves the oil vehicle comparatively untouched.

"The effect, then, of passing a wash or spirits of wine over the naked surface of delicate, transparently-painted pictures—such, for instance, as those of Claude Lorraine—may be easily imagined; it is to reduce them immediately to things of threads and patches; portions, for instance, will be entirely effaced, others half obliterated, while others will be scarcely, if at all, injured; but the final result, it is scarcely necessary to say, will be absolute, irretrievable deterioration.

"In order to protect the delicate and easily-injured surfaces of oil pictures, and for other legitimate reasons, they are always, sooner or later, covered over with superadded varnish, often thickly piled up, from time to time, one over another, during long periods. These coats of old varnish, however, are liable, sooner or later, to become dirty and opaque, and so more or less to conceal the painting beneath; and then it becomes requisite to remove them, either entirely or partially. If nothing but the right kind of varnish has been used the process is a perfectly simple and safe one; but if improper kinds of varnish and other 'nostrums' have been at different times applied, the operation may become very complicated and difficult. The practical skill and, above all, the long acquired experience of a conscientious and painstaking picture cleaner is then imperatively required. The matter may then be not inaptly compared to the surgical treatment of a human being. The really accomplished picture cleaner acquires, as it were, much the same kind of intuitive insight into the state of a picture as an eminent surgeon does into that of the patient upon whom he is to operate; and just as the learned practitioner saves his patient and restores him to health, while the ignorant, blundering quack may kill him with a single touch, so a picture may be rescued from the inevitable deteriorating influences of time and accident, and restored, as it were, to fresh life, or blotted out for ever by presumptuous and unskilful hands in the twinkling of an eye.

"There is only one kind of varnish proper to be applied to oil pictures—pure mastic dissolved in turpentine; for, in addition to other superior qualities, this varnish may at any time be removed in a peculiarly safe and convenient manner. For centuries this varnish has been known and universally employed as the pre-eminently fit and proper one. Unfortunately, it was reserved for this country of ours, at the period of its densest ignorance in matters artistic, to give rise to a race of reckless and stupid quacks, by whom a fatal admixture—worse than poison—was brought into almost universal use, and made to supersede the only true and proper vehicle before alluded to. Towards the end of the last century, more especially, it became the frequent prac-

tice with English picture cleaners and restorers to mix oil with the varnishes with which they covered ancient and modern pictures alike. Two overwhelming evil results ensue from the use of oil varnish. In process of time it gradually darkens and loses its transparency. According to the dose and kind of oil mixed with the varnish, and the thickness of the superadded coats, it gradually passes through every tint, from pale yellow down to deep chestnut, brown or black, while, at the same time, every year that it remains it becomes harder, tougher, more concrete, and difficult to remove. This varnish, when much oil enters into its composition, is, in fact, identical in composition with the vehicle used in the painting of the picture, and when applied directly on the uncovered surface of the work, and allowed to remain for many years, it becomes, as it were, part and parcel of the painted surface itself, and cannot be removed by any known means without injury to it. In some rare cases it is quite hopeless to attempt to remove the varnish, and the picture so covered must be left to languish from year to year, and finally perish in a sort of Stygian fog.

"Now, perhaps, the worst offender in this serious matter was the first keeper of our own National Gallery, the late Mr. Segraver, an eminent picture dealer of forty or fifty years ago. This disastrous person invented an oil varnish of his own, which he called, *par excellence*, 'the Gallery varnish.' The oil which he mingled with the varnish was of the worst possible kind, and the dose seems to have been of the largest. It was boiled linseed, or 'drying oil'—a kind of oil which actually undergoes slow spontaneous combustion, and in process of time becomes absolutely carbonized and black. With this diabolical mixture he literally covered over and over again nearly all the great masterpieces in the National Gallery, and probably also hundreds of other admirable pictures in the country houses and galleries of the gentry and nobility throughout England. For twenty years more the fatal effects of this varnish have been recognized by all really well-informed lovers of art, and successive keepers and directors of the National Gallery have made attempts to remove it from the pictures which had suffered the most from its effects. Now the removal of this varnish from every picture to which it has been applied is quite imperative, and every year—nay, every day—which is lost, increases the risk and difficulty of the operation, inasmuch as the blackening and hardening are ever in progress.

SOME REMARKS ABOUT PHOTOGRAPHING INTERIORS, AND ABOUT PORCELAIN BATHS.

BY RICHARD DOUGLASS.

A few weeks ago I was called upon to make some views of interiors, whose light was so dim that my plates were covered with stains from long standing. I was about to give the job up hopelessly, when presently a bright idea occurred to me. I asked if they had any glycerine in the house. A small bottle of it was procured, and a few drops were put into my collodion and silver. The subsequent plates were free from stains, although left in the camera for from thirty to forty minutes. Curiously enough, the high lights, such as windows, bright objects reflected from mirrors, were distinctly visible on the plates just as they came out of the plate-holder. The developer brought out the rest without fogging, save a slight veiling on the windows. This phenomena I never saw explained. Can anyone explain it?

Mr. Casey Lee, in his excellent work on photography, says about porcelain baths: "If there is the slightest flaw in the glazing inside, the solution will penetrate it and gradually saturate the whole of the porous biscuit which makes the body of the vessel, between the inside and outside glazing. This not only involves a great loss of expensive silver solution, but after a time the outside glazing also probably cracks, and some day the operator finds his bath empty."

Last year I carelessly broke my rubber view-bath, and used a porcelain one in its stead, having before heard that silver would penetrate porcelain, but I thought my bath an exception. I trusted it with my solution over night, and even left it in for weeks. I suffered no inconvenience from it for about nine months, but lately, when taking a view, I noticed some diminution of solution. I suspected nothing, so refilled it, and work went on. An hour after work was done I returned to it and found it empty. This justifies what Lea says in his manual. Let those who use porcelain silver baths be careful to select perfect ones, or dispense with them entirely.

CRYOLITE OPALINE GLASS.

CRYOLITE was discovered toward the end of the last century in a bay in Arksut Fiord, West Greenland, where it constitutes a large bed or vein in the gneiss of about three hundred feet in length and eighty feet in thickness. The name is derived from two Greek words meaning "ice" and "stone," and is applied because of the fusibility of the mineral in the flame of a candle. It was supposed to be sulphate of barytes until examined by Abildgaard, who found it to contain fluoric acid. Subsequently Klaproth detected soda in its composition. It was not, however, until 1850, when Jules Thomson discovered that the mineral could be easily decomposed either by the dry or wet way with lime and the calcareous salts, that it came into industrial use. In appearance, cryolite is snow white, partially transparent, of vitreous lustre, and brittle texture. Its hardness is 2.5, specific gravity 3; and it cleaves in three directions, two of which are rectangular.

From cryolite, aluminum, alum, caustic soda, and glass of a peculiar quality are obtained. About six thousand tons of the mineral are yearly brought to this country for soda manufacture. The glass is produced in Philadelphia under the name of "hot cast porcelain," and, when made of pure cryolite, is milky white in hue, and slightly transparent. Impure cryolite yields an opaque glass, closely resembling marble. The mixture for milky glass consists of—

Oxide of zinc	1 part
Cryolite	4 parts
Sand	10 "

This is melted in pipe-clay pots, which are not attacked by the fluo-silicic acid disengaged. The glass is very hard, remarkably solid, and is not attacked by strong acids, even when pulverized. These properties are doubtless due to the presence of undecomposed cryolite. With a small quantity of the mineral, the glass is brilliant, and refracts light strongly; with a greater quantity it becomes opalescent; and, finally, on more cryolite being added, the glass turns opaque, and closely resembles porcelain.—*Scientific American.*

ALKALINE DEVELOPMENT.

BY M. ERNEST BOVIN.*

Nor only is the presence of nitrates of silver unnecessary in alkaline development, but it seems actually to be injurious to the process. Alkaline development is more generally employed for dry plates than in the wet process, and is especially suitable for emulsion and bromide collodion. Chemists appear to be divided in opinion upon the theory of this manner of development, but there are, nevertheless, certain points which are generally conceded.

Thus it has been completely proved that the alkaline salts exercise an oxidizing action, ammonia acts upon the bromide with which it is mixed, transforms it into oxybromide, and eliminates a portion of the bromine. This simple body combines with a portion of a base, and forms compounds of a very stable character and very difficult to oxidize. It unites with iodine and iodides, and forms a compound which corresponds to bi-bromide, and remains fixed and unoxidizable. This prevents the formation of fog, which would

infallibly result from the contact of iodide of silver with the alkaline salt, a contact which would transform the entire film into oxy-iodide of silver, absolutely identical with that produced by the chemical action of luminous rays, and would consequently blacken throughout, under the influence of the reducing agent. This effect is to be obtained in the case of a very prolonged exposure when bromo-iodized collodion is employed; bromine, which has less affinity for oxygen than iodine, separates from the oxy-bromide, spreads over the plate, and communicates to it a greyish tint, which is generally known under the name of solarisation.

The alkaline salt exercises its oxidising action upon the oxy-iodide of silver produced by the chemical action of the light, and transforms it into pure oxide; the iodine displaced permits the reducing agent to decompose the oxide by absorbing its oxygen, and leaving a deposit of metallic silver, an action which continues until the total reduction of the oxy-iodide resulting from the chemical action of the luminous rays has taken place.

Alkaline development is much more energetic and much more active and powerful than acid development; its employment in dry processes renders it precious, and permits one to reduce in a material degree the duration of the exposure.

The bromide in alkaline development is a moderator of incontrollable utility; it plays exactly the same rôle that acetic acid performs in the ordinary development of wet plates; bromide should be employed in greater quantity in warm weather and when the exposure has been long, and in small quantity when it is cold and the exposure has been short. It is the bromide which clears up a picture and prevents any accidental fogging.

In alkaline development I have replaced with very great advantage pure ammonia, carbonate of ammonia, the saccharates of lime and potash, with glucoside of ammonium; I employ the latter in precisely the same manner as ammonia, that is to say, in doses of drops only in the developer. I obtain with this glucoside of ammonium much more intensity, vigour, and regularity in development than is the case when the former substances are employed. The glucoside may also be used in addition to ammonia to impart increased vigour to the cliché when the details have appeared, and I may say that the results thus secured are really remarkable. It is always advisable to employ a few drops of bromide at the same time as the glucoside, that which I prefer being the bromide of ammonium.

I prefer the glucoside in the manner following:—In 100 cubic centimetres of liquid ammonia I dissolve 10 grammes of grape sugar (glucose); I allow the solution to remain for some days, filter, and add 100 cubic centimetres of water. I filter once more, and preserve it in a stoppered bottle. The glucoside does not seem to deteriorate on keeping.

ON THE IMMEDIATE AND POSSIBLE EFFECTS OF CERTAIN RECENTLY PROPOSED ADDITIONS TO THE NEGATIVE BATH.

BY W. HOWARD.*

THE last paper was devoted to considering the effects of an agent which came within the literal range of the wording adopted in the title affixed to the series. In the present article regard is given to other agents, which, though not falling so entirely within the literal boundaries of the title, are at least germane to the general subject, inasmuch as by decompositions naturally taking place in the negative bath in the course of time, or more directly induced by additions to the collodion, they sooner or later affect the negatives produced from it. These agents are the nitrite and acetate of silver, both of which salts are formed in the bath by the reactions set in motion by ordinary use. The nitrite is the first stage in the reduction of the nitrate by the alcohol and ether introduced by every plate immersed. The acetate results from the acetic acid produced by the full oxidation of part of the alcohol and ether,

* *Mentour de la Photographie.*

* Continued from page 385.

which then combines with any silver present in the metallic state or in the transition state of oxide.

It has recently been ascertained that some of our collodion manufacturers add nitrites (probably of the alkalies) to the article they produce, with a view of increasing its sensitiveness. Some of our transatlantic friends are of opinion that a similar result is achieved by using a collodion containing acetic acid. Amongst many English photographers there prevailed a few years ago a practice of adding acetate of soda to the negative bath, with a like object in view. Of late, this agent has fallen into disuse, and has, if I am not much mistaken, been condemned as injurious by many able workers.

The trials which I have made with the two salts were conducted in connection with an alkaline carbonate bath, prepared in the manner previously described. These experiments were divided into two classes—*i. e.*, those in which the accelerating agent used was added to the collodion in the form of an alkaline nitrite or acetate, and those in which the nitrite or acetate of silver, carefully prepared, was added directly to the bath. The addition of nitrite of potash to the collodion, in the proportion of about two grains per ounce, produced very marked results. The time required for exposure was very considerably shortened, and the image developed with great rapidity; but, as a serious drawback, the rapidity of exposure gained was accompanied by dense fog. Repeated trials gave a similar result—very short exposures, but always accompanied by fog. This was just what I had anticipated, for in my experience of the matter I have noted that even neutral baths, in which, as I was positively aware, nitrite of silver happened to be present, invariably produced foggy plates. This result is doubtless due to the readiness with which the silver nitrite is reduced by light in the presence of organic matter, this property enabling it to act upon the other compounds present by assisting readily in the molecular or chemical disturbance set up by exposure, and rendering the entire surface of the plate more or less liable to receive a metallic deposit upon development. The addition of silver nitrite to the bath, in quantities not exceeding one grain per ounce, gave results which agreed in every respect with the above statements.

One other result, not at all desirable, was brought into notice after a very few plates capable of introducing nitrite into the bath had been immersed—this was the production of pinholes. This effect was also produced in the bath to which the silver nitrite had been previously added. A slight distinction may be made between the two modes of working, *viz.*, the addition of an alkaline nitrite to the collodion, and its subsequent and consequent decomposition into silver nitrite; and an alkaline nitrate upon immersion in the bath produced pinholes in the plates in a shorter time than did the direct addition of silver nitrite to the bath. This fact of the ready production of pinholes by collodion containing nitrites has, I think, been noticed by other workers, although they have not, so far as I am aware, made mention of any peculiar liability to fog following upon its use. My own impression is, that when working with an ordinary bath, which is pretty safe to be in an acid condition, there is no formation of nitrite of silver; and this opinion is based upon these grounds: the free acid usually present in the bath is nitric acid, and that this acid simply decomposes like the nitrite in the collodion, producing an inert nitrate, and liberating nitrous acid, which is again in turn decomposed by the large quantity of water present, forming a small quantity of nitric acid and some nitric oxide. Taking this view of the matter, it will appear that any increased sensitiveness which follows upon the use of a collodion containing nitrites in conjunction with an ordinarily acid bath is due to the decrease in the quantity of free nitric acid (restrainer) present. In an alkaline or neutral bath the nitrite of silver can readily form when such a collodion is used, and it asserts its presence by greatly increased rapidity of exposure, and great liability to fog. The pinhole aspect of the

result remains to be considered. We have in the case of an ordinary bath increased liability to this annoyance, and in the case of an alkaline carbonate bath which, under ordinary circumstances (*i. e.*, the use of a collodion free from nitrites), appears to be free from this defect, its not very remote occurrence. In the first case this may be traced—even assuming that no silver nitrite is produced—to the circumstance that the inert, but fairly soluble, nitrates usually produced are introduced with greater rapidity, and consequently the less soluble iodo-nitrate is precipitated at an earlier period.

In the case of the alkaline carbonate bath my observations had led me not to the conclusion that iodo-nitrate did not form in it, but only to consider that the presence of the free alkaline body retarded its precipitation. When, however, upon the positive introduction of more than the usual quantity of soluble nitrates, and also some nitrite of silver, a body more soluble, indeed, than the iodo-nitrate, but, as compared with salts generally, very slightly soluble, I was not at all surprised at the result, the above considerations appearing ample explanation of its appearance on the plate.

Now, bearing in mind the fact that an alkaline bath readily undergoes reduction by the agency of the alcohol and ether imparted to it, and that silver nitrite must at times make its appearance, I should not be much astonished if those who make a trial of it should now and then be troubled with fog and pinholes. The remedy for such a condition I have already pointed out: add nitric acid, and a fresh quantity of carbonate of silver afterwards.

The use of acetate of silver in conjunction with this bath gave very favourable results, not much difference being observable in the results obtained by using a collodion containing an alkaline acetate, or by using a bath containing acetate of silver. This last was added to the bath in the proportion of about three grains per ounce. The result was a reduction of exposures to about half the time required by a faintly acid bath, and very considerable when compared with an alkaline one. No fog produced, and tendency to form pinholes avoided, even on continued working. The accelerated exposures are attributable, no doubt, as in instance of the nitrite, to the influence exercised by the acetate of silver in more readily determining decomposition in the camera. The freedom from fog observed arises very probably from the greater stability of this salt, in consequence of which the reduction effected by the developer is not so violent and instantaneous in character. The oxide of silver is more readily reduced than the nitrite, and the nitrite more readily than the acetate; hence new baths made with over-fused nitrate containing oxide and nitrite of silver invariably produce fog, while very old baths, in which these bodies have been converted into acetate, nearly always work with rapidity and cleanliness of result.

I think that while no immediate difference is made by using acetates in the collodion, the preferable plan is to introduce the acetate of silver directly into the bath. This may be done by adding acetate of soda; but seeing that this will falsify the argometer reading in an unusual degree, and also that it is thus quite possible to introduce sulphate of silver, as commercial acetates are generally contaminated with sulphates, it is advisable to prepare the acetate of silver by decomposing a strong and hot solution of silver nitrate with soda acetate, also in a strong solution, filtering, and permitting to crystallize. The crystals may be washed with distilled, or silvered and sunned water, and allowed to dry spontaneously in the dark room, being carefully protected from dust. They can then be weighed and added accurately to the bath, thus avoiding the introduction of sulphates, or unnecessary inert nitrates, either of which might induce the pinhole nuisance.

In conclusion, I may remark that the much talked of procedure adopted by M. Boiminas is very probably chiefly dependent on the addition of acetates to a neutral bath, or an alkaline one like Mr. Eliot's.

AN IMPORTANT IMPROVEMENT IN EMULSIONS.

EMULSION photography has progressed much more slowly than, having regard to its simple and scientific character, might have been anticipated. The simplicity and attractiveness of using a single preparation for coating plates containing all the sensitive salts within itself, instead of obtaining these salts by immersing a coated plate in a solution where the sensitive layer is formed by double decomposition between the silver salt in the bath and the haloid salt in film, would, one might easily imagine at the outset, have given emulsion practice an unquestionable claim to preference. A variety of minor drawbacks have, however, served effectually to check the progress of emulsion in general favour and application. One of the primary troubles arose from the fact that the sensitive salts were formed in the emulsion by double decomposition, and hence it contained other salts besides the sensitive salts of silver, and these other salts were not only useless, but injurious, crystallizing on the film, and becoming a fruitful source of pinholes. We remember well when, something like seventeen years ago, we conceived the brilliant idea of producing an emulsion containing the sensitive salts, we added nitrate of silver in about its equivalent proportion to bromo-iodized collodion. With this we coated a plate, exposed it when set, soaked it a few minutes in water to prepare it for the developer flowing freely, and then developed first in plain pyro, and then with acid pyro and silver. We obtained a very respectable image, but it was covered with pinholes. As, besides this drawback, no especial advantage had been gained, we reluctantly gave up, for the time, emulsion work, after a few more experiments. We simply recal this brief essay to remark that similar difficulties beset emulsion work even after Messrs. Sayce and Bolton had given the bromide emulsion a practical form.

Many very capable photographers have, in the meantime, devoted themselves to improving the emulsion processes, which have now attained a high state of excellence. In collodion emulsions an efficient, but certainly somewhat troublesome, method of washing serves to eliminate the nitrates formed by double decomposition in the emulsion. In gelatine emulsions a similar plan has been adopted from the first. Two methods have been adopted in gelatine emulsions to remove the nitrates. The first, which is very efficient and scientific, is that by dialysis: a process which readily permits of the separation of crystalloid bodies from colloid bodies. But this process is slow and troublesome, and more essentially suited to the practice of the amateur than to that of the manufacturer working on a large scale. The other method is that patented by Mr. Kennett, in

which the emulsion, when formed, is poured in a thin layer in a dish, and when set is cut up into strips. These strips are then washed in cold water, which is supposed to wash out of them all the soluble salts, consisting of the nitrates, leaving intact the insoluble bromide of silver entangled in the gelatine. In practice, this method appears to answer very well, judging from the excellent work we have seen produced on Mr. Kennett's plates, and with his pellicle. Without disparaging this method, however, we venture to think that a new method, recently brought under our attention by Messrs. Wratten and Wainwright, is an improvement on all prior methods. Their method simply consists in washing the sensitive gelatine emulsion with alcohol. This, it will be seen, has no soluble action on the gelatine, nor, at first sight, it would seem, should it have on the nitrate of ammonia or other base which is to be removed. But another very important principle comes into operation, in virtue of which the nitrates are effectually removed. Alcohol is very greedy of water, and will absorb it whenever it is brought into contact with it, even though it be in the possession of such a hygroscopic body as gelatine. On placing the gelatine emulsion in contact with alcohol, it is rapidly robbed of its water, and with the water go the soluble salts which were in solution in the water. A gelatine pellicle is thus rapidly obtained without water and without the nitrates which had been dissolved in the water. The principle is scientific and elegant, and the practical issue is most perfect, as we can testify. Mr. Wratten, of the firm of Wratten and Wainwright, to whom this discovery is due, has shown us results, and enabled us to test the mode of procedure, which appears to be in every respect satisfactory.

As the use of gelatine emulsion is by no means common or familiar amongst photographers generally, a resume of the principles and practice as employed by Mr. Wratten will here be found useful; and in presenting it to our readers, we may remark, as giving it the authority of a practised and successful hand, that the method of procedure is due to that gentleman. In the preparation of a gelatine emulsion—the simplest and least complex of all forms of emulsion, and the easiest to compound—the elements usually employed are gelatine, bromide of ammonium, potassium, or any other base, and nitrate of silver. The requisite quantity of bromide of any base that may be chosen is first dissolved in a portion of the water, the gelatine added, and left to soak for a certain time. The whole is then placed in a receptacle containing water of (say) 100° temperature, and solution of the gelatine is quickly brought about. We have now a solution of bromised gelatine which bears a strict analogy to bromised collodion. To form the emulsion from this compound it is now necessary to dissolve the proper quantity of nitrate of silver in the remainder of the water, raise it to the same temperature as the bromised gelatine, and then stir it gradually and carefully into the latter. When the mixture is made, insert the stopper and shake vigorously for a minute or two, to bring the two elements out of which the sensitive salt is to be formed into contact with each other. Hereupon double decomposition is set up, and in order that this may be the more perfectly completed the emulsion is kept at a temperature of from 90° to 100° for three or four hours. This being properly completed, the emulsion contains two elements, the one bromide of silver, the true sensitive material, the other an encumbrance worse than useless, in fact—to use Palmerston's definition of matter in the wrong place—dirt. This must be eliminated, or it will crystallize upon the film, and ruin it. There have been, hitherto, two recognized methods of effecting this operation, the one, as we have already explained, that of dialysis, for which we are indebted to Mr. Josiah King, of the Bombay Civil Service; the other, as we have explained, consists in pouring of emulsion into a flat dish, allowing it to set, and washing it with a large quantity of water, for which we are indebted to Mr. Kennett. But it may be said of both

these methods that they are really, more or less, "rule of thumb;" although with due care and time given, quite practical in the result. We have now, however, a third method, that of Mr. Written, which is not only more scientific than either of the above mentioned, but more simple and practical, and it is, we believe, incomparably more speedy in action. It is a well-known fact that alcohol has a strong affinity for water. In alcohol, then, we find the means of effecting the desirable and necessary operation of eliminating the useless salts. Take, for example, five ounces of emulsion compound by any of the published formulæ, add thereto ten ounces alcohol absolute, shake vigorously, and stand aside. In a few minutes the water will have left the gelatine to unite with the alcohol, carrying the mischievous nitrate salt with it, and the solution may be poured off in volume nearly equal to the total quantities of alcohol and water that have been employed. It is well to stand the bottle upside down, and let the gelatine drain into a larger receptacle, as it takes a little time to empty its little cells. When perfectly drained, it suffices to add the quantity of water employed in the first instance; let it soak a little while, and then dissolve the whole by heat as before. It is now ready for use, and the quantity of alcohol already in the film will be found of utility in causing the film to set more rapidly than is the case when water alone is employed; in fact, the plates may be placed on end to dry in about twenty minutes after coating. It may be urged by some that the additional cost is a legitimate objection to the use of this method; but if we set against this item the saving of time, and the prevention of failure which this practically amounts to, the objection has but little weight. Moreover, we have found that a good quality of methylated alcohol is as effective as the pure; hence, the extra expense is not great.

To all interested in dry plate work, and especially in emulsion work, we think the improvement we have described will prove most valuable as aiding them to secure simplicity and certainty in producing plates of the greatest sensitiveness, giving results of very high quality. As the film of gelatine is singularly free from grain, reticulation, or texture, the negatives are admirably well adapted for enlargement.

PORTRAIT LENSES AND LANDSCAPE WORK, ETC.

THE following letters will be read with interest by many of our readers. Similar questions to those raised in the letter of "Tyro" are frequently reaching us, and we answer briefly in the column devoted to answering queries. It occurred to us that a fuller answer from an optician of the highest reputation would be useful, and therefore submitted the letter to Mr. Dallmeyer, whose answer we append:—

"SIR.—If you, or any of your readers who may possess the needful optical knowledge, would give the required information as to distance of separation and position of stop, I think it would prove very useful to many who, like myself, possess several good single landscape lenses, and wish to try to combine them, so as to make a double and quick-acting short focus lens for rapid work. Happening to see in an optician's catalogue that the two lenses of his double combination rapid lens could be used singly as long focus landscape lenses, it occurred to me that probably if so, two single combination lenses used in combination might give a satisfactory quick lens of short focus. I happened to have an 8½ inch focus, 2½ diameter, and a 12 inch focus, 2½ inch diameter lenses—screwing into either end of the same tube—which were made for me many years ago by Mr. A. Ross. I have just made an experiment with one of these lenses in each end of the tube, and the stop between them. The separation is, of course, great, and the stop near one and far from the other lens, but yet it has given a fair picture, with a very short exposure, and I feel sure, if I knew

the proper separation of two such lenses, and the proper position of the stop between them, it would give very good results.

"If you could give a simple formula by which any of your readers could reckon for themselves the proper distance apart, and the proper position of stop for landscape lenses of various foci, and various diameters to be used thus in combination, I am sure many of your readers would thank you, and find themselves able to make excellent quick-acting lenses from their old single view lenses of the usual plano-convex form. The formula should be applicable both to lenses of equal focal length and of differing focal lengths to be used together.—I am, yours very obliged,
TYRO."

"DEAR SIR,—I have read your correspondent's letter, and return it herewith. No definite formula can be given as he desires; the separation or the interval between two combinations depends upon their forms as much as their diameters and foci. You may remember years ago Mr. Rothwell suggested a combination composed of two plano-convex achromatic lenses for the cure of distortion, the stop to be positioned in relation to their foci; but the field of view was so much curved that it proved a failure; moreover, single combination view lenses so employed are affected with spherical aberration for the central pencils, and require the use of comparatively small stops on that account. It is one thing for an optician to say that one of the combinations of a given lens can be used as a single combination; it is quite another to say that, so used, it is the best single lens that can be made.—In haste, yours sincerely,
"J. H. DALLEMEYER."

"P.S.—If the correspondent's view lenses have their apertures, or rather diameters and foci, in the same proportion, he would probably get the best result out of any given pair by separating them at a distance equal to the sum of their diameters, and then by placing the stop in a position proportionate to those diameters between the lenses.

A PORTRAIT DEVELOPER.

IN a recent number of *La Moniteur de la Photographie* M. Flament gives the details of a developer with which he tells us he has succeeded in producing very fine portraits. He says:—

"Having lately had occasion to take a series of portraits of friends, I made use of an iron developer which has given me several negatives of great beauty. The solution is nothing very particular, but it yields such good results that I cannot help thinking amateurs will be glad to know of the formula, especially as the solution is one which may be kept some days in good condition, a convenience to others, like myself, who are not working every day.

"Developers redden a short time after preparation, and when in contact with the air become charged with acetic acid, to the detriment of their reducing action. To prevent this inconvenience, and in order still to be able to make use of the bath, which in this condition acts rather slowly, I deem it well not to add the acetic acid and alcohol until I make use of the solution.

"I keep a stock of a saturated solution of double proto-sulphate of iron (this salt is soluble, cold, in twice its weight of water), and to twenty cubic centimetres of the solution I add—

Pure or rain water...	...	80 cubic cents.
Acetic acid	10 "
Alcohol	5 "

The developer in this condition is ready for use. At the same time I deem it well to add, just before the solution is applied to the film, a few drops of a solution of acetate of soda of five per cent. strength, which I have reason to think improves the delicacy of the cliché. The acetate of soda does not, however, in any way accelerate the action of the developer."

these methods that they are really, more or less, "rule of thumb;" although with due care and time given, quite practical in the result. We have now, however, a third method, that of Mr. Wratten, which is not only more scientific than either of the above mentioned, but more simple and practical, and it is, we believe, incomparably more speedy in action. It is a well-known fact that alcohol has a strong affinity for water. In alcohol, then, we find the means of effecting the desirable and necessary operation of eliminating the useless salts. "Having lately had occasion to take a series of portraits of friends, I made use of an iron developer which has given me several negatives of great beauty. The solution is nothing very particular, but it yields such good results that I cannot help thinking amateurs will be glad to know of the formula, especially as the solution is one which may be kept some days in good condition, a convenience to others, like myself, who are not working every day.

"Developers redden a short time after preparation, and when in contact with the air become charged with acetic acid, to the detriment of their reducing action. To prevent this inconvenience, and in order still to be able to make use of the bath, which in this condition acts rather slowly, I deem it well not to add the acetic acid and alcohol until I make use of the solution.

"I keep a stock of a saturated solution of double proto-sulphate of iron (this salt is soluble, cold, in twice its weight of water), and to twenty cubic centimetres of the solution I add—

Pure or rain water...	80 cubic cents.
Acetic acid ...	10 "
Alcohol ...	5 "

The developer in this condition is ready for use. At the same time I deem it well to add, just before the solution is applied to the film, a few drops of a solution of acetate of soda of five per cent. strength, which I have reason to think improves the delicacy of the cliché. The acetate of soda does not, however, in any way accelerate the action of the developer."

AN IMPORTANT IMPROVEMENT IN EMULSIONS.

EMULSION photography has progressed much more slowly than, having regard to its simple and scientific character, might have been anticipated. The simplicity and attractiveness of using a single preparation for coating plates containing all the sensitive salts within itself, instead of obtaining these salts by immersing a coated plate in a solution where the sensitive layer is formed by double decomposition between the silver salt in the bath and the haloid salt in film, would, one might easily imagine at the outset, have given emulsion practice an unquestionable claim to preference. A variety of minor drawbacks have, however, served effectually to check the progress of emulsion in general favour and application. One of the primary troubles arose from the fact that the sensitive salts were formed in the emulsion by double decomposition, and hence it contained other salts besides the sensitive salts of silver, and these other salts were not only useless, but injurious, crystallizing on the film, and becoming a fruitful source of pinholes. We remember well when, something like seventeen years ago, we conceived the brilliant idea of producing an emulsion containing the sensitive salts, we added nitrate of silver in about its equivalent proportion to bromo-iodized collodion. With this we coated a plate, exposed it when set, soaked it a few minutes in water to prepare it for the developer flowing freely, and then developed first in plain pyro, and then with acid pyro and silver. We obtained a very respectable image, but it was covered with pinholes. As, besides this drawback, no especial advantage had been gained, we reluctantly gave up, for the time, emulsion work, after a few more experiments. We simply recal this brief essay to remark that similar difficulties beset emulsion work even after Messrs. Sayce and Bolton had given the bromide emulsion a practical form.

Many very capable photographers have, in the meantime, devoted themselves to improving the emulsion processes, which have now attained a high state of excellence. In collodion emulsions an efficient, but certainly somewhat troublesome, method of washing serves to eliminate the nitrates formed by double decomposition in the emulsion. In gelatine emulsions a similar plan has been adopted from the first. Two methods have been adopted in gelatine emulsions to remove the nitrates. The first, which is very efficient and scientific, is that by dialysis: a process which readily permits of the separation of crystalloid bodies from colloid bodies. But this process is slow and troublesome, and more essentially suited to the practice of the amateur than to that of the manufacturer working on a large scale. The other method is that patented by Mr. Kennett, in

which the emulsion, when formed, is poured in a thin layer in a dish, and when set is cut up into strips. These strips are then washed in cold water, which is supposed to wash out of them all the soluble salts, consisting of the nitrates, leaving intact the insoluble bromide of silver entangled in the gelatine. In practice, this method appears to answer very well, judging from the excellent work we have seen produced on Mr. Kennett's plates, and with his pellicle. Without disparaging this method, however, we venture to think that a new method, recently brought under our attention by Messrs. Wratten and Wainwright, is an improvement on all prior methods. Their method simply consists in washing the sensitive gelatine emulsion with alcohol. This, it will be seen, has no soluble action on the gelatine, nor, at first sight, it would seem, should it have on the nitrate of ammonia or other base which is to be removed. But another very important principle comes into operation, in virtue of which the nitrates are effectually removed. Alcohol is very greedy of water, and will absorb it whenever it is brought into contact with it, even though it be in the possession of such a hygroscopic body as gelatine. On placing the gelatine emulsion in contact with alcohol, it is rapidly robbed of its water, and with the water go the soluble salts which were in solution in the water. A gelatine pellicle is thus rapidly obtained without water and without the nitrates which had been dissolved in the water. The principle is scientific and elegant, and the practical issue is most perfect, as we can testify. Mr. Wratten, of the firm of Wratten and Wainwright, to whom this discovery is due, has shown us results, and enabled us to test the mode of procedure, which appears to be in every respect satisfactory.

As the use of gelatine emulsion is by no means common or familiar amongst photographers generally, a resume of the principles and practice as employed by Mr. Wratten will here be found useful; and in presenting it to our readers, we may remark, as giving it the authority of a practised and successful hand, that the method of procedure is due to that gentleman. In the preparation of a gelatine emulsion—the simplest and least complex of all forms of emulsion, and the easiest to compound—the elements usually employed are gelatine, bromide of ammonium, potassium, or any other base, and nitrate of silver. The requisite quantity of bromide of any base that may be chosen is first dissolved in a portion of the water, the gelatine added, and left to soak for a certain time. The whole is then placed in a receptacle containing water of (say) 100° temperature, and solution of the gelatine is quickly brought about. We have now a solution of bromised gelatine which bears a strict analogy to bromised collodion. To form the emulsion from this compound it is now necessary to dissolve the proper quantity of nitrate of silver in the remainder of the water, raise it to the same temperature as the bromised gelatine, and then stir it gradually and carefully into the latter. When the mixture is made, insert the stopper and shake vigorously for a minute or two, to bring the two elements out of which the sensitive salt is to be formed into contact with each other. Hereupon double decomposition is set up, and in order that this may be the more perfectly completed the emulsion is kept at a temperature of from 90° to 100° for three or four hours. This being properly completed, the emulsion contains two elements, the one bromide of silver, the true sensitive material, the other an encumbrance worse than useless, in fact—to use Palmerston's definition of matter in the wrong place—dirt. This must be eliminated, or it will crystallize upon the film, and ruin it. There have been, hitherto, two recognized methods of effecting this operation, the one, as we have already explained, that of dialysis, for which we are indebted to Mr. Josiah King, of the Bombay Civil Service; the other, as we have explained, consists in pouring of emulsion into a flat dish, allowing it to set, and washing it with a large quantity of water, for which we are indebted to Mr. Kennett. But it may be said of both

these methods that they are really, more or less, "rule of thumb;" although with due care and time given, quite practical in the result. We have now, however, a third method, that of Mr. Wratten, which is not only more scientific than either of the above mentioned, but more simple and practical, and it is, we believe, incomparably more speedy in action. It is a well-known fact that alcohol has a strong affinity for water. In alcohol, then, we find the means of effecting the desirable and necessary operation of eliminating the useless salts. Take, for example, five ounces of emulsion compound by any of the published formulae, add thereto ten ounces alcohol absolute, shake vigorously, and stand aside. In a few minutes the water will have left the gelatine to unite with the alcohol, carrying the mischievous nitrate salt with it, and the solution may be poured off in volume nearly equal to the total quantities of alcohol and water that have been employed. It is well to stand the bottle upside down, and let the gelatine drain into a larger receptacle, as it takes a little time to empty its little cells. When perfectly drained, it suffices to add the quantity of water employed in the first instance; let it soak a little while, and then dissolve the whole by heat as before. It is now ready for use, and the quantity of alcohol already in the film will be found of utility in causing the film to set more rapidly than is the case when water alone is employed; in fact, the plates may be placed on end to dry in about twenty minutes after coating. It may be urged by some that the additional cost is a legitimate objection to the use of this method; but if we set against this item the saving of time, and the prevention of failure which this practically amounts to, the objection has but little weight. Moreover, we have found that a good quality of methylated alcohol is as effective as the pure; hence, the extra expense is not great.

To all interested in dry plate work, and especially in emulsion work, we think the improvement we have described will prove most valuable as aiding them to secure simplicity and certainty in producing plates of the greatest sensitiveness, giving results of very high quality. As the film of gelatine is singularly free from grain, reticulation, or texture, the negatives are admirably well adapted for enlargement.

PORTRAIT LENSES AND LANDSCAPE WORK, ETC.

THE following letters will be read with interest by many of our readers. Similar questions to those raised in the letter of "Tyro" are frequently reaching us, and we answer briefly in the column devoted to answering queries. It occurred to us that a fuller answer from an optician of the highest reputation would be useful, and therefore submitted the letter to Mr. Dallmeyer, whose answer we append:—

"SIR.—If you, or any of your readers who may possess the needful optical knowledge, would give the required information as to distance of separation and position of stop, I think it would prove very useful to many who, like myself, possess several good single landscape lenses, and wish to try to combine them, so as to make a double and quick-acting short focus lens for rapid work. Happening to see in an optician's catalogue that the two lenses of his double combination rapid lens could be used singly as long focus landscape lenses, it occurred to me that probably if so, two single combination lenses used in combination might give a satisfactory quick lens of short focus. I happened to have an 8½ inch focus, 2½ diameter, and a 12 inch focus, 2½ inch diameter lenses—screwing into either end of the same tube—which were made for me many years ago by Mr. A. Ross. I have just made an experiment with one of these lenses in each end of the tube, and the stop between them. The separation is, of course, great, and the stop near one and far from the other lens, but yet it has given a fair picture, with a very short exposure, and I feel sure, if I knew

the proper separation of two such lenses, and the proper position of the stop between them, it would give very good results.

"If you could give a simple formula by which any of your readers could reckon for themselves the proper distance apart, and the proper position of stop for landscape lenses of various foci, and various diameters to be used thus in combination, I am sure many of your readers would thank you, and find themselves able to make excellent quick-acting lenses from their old single view lenses of the usual plano-convex form. The formula should be applicable both to lenses of equal focal length and of differing focal lengths to be used together.—I am, yours very obliged,

TYRO."

"DEAR SIR,—I have read your correspondent's letter, and return it herewith. No definite formula can be given as he desires; the separation or the interval between two combinations depends upon their forms as much as their diameters and foci. You may remember years ago Mr. Rothwell suggested a combination composed of two plano-convex achromatic lenses for the cure of distortion, the stop to be positioned in relation to their foci; but the field of view was so much curved that it proved a failure; moreover, single combination view lenses so employed are affected with spherical aberration for the central pencils, and require the use of comparatively small stops on that account. It is one thing for an optician to say that one of the combinations of a given lens can be used as a single combination; it is quite another to say that, so used, it is the best single lens that can be made.—In haste, yours sincerely,

"J. H. DALLEMEYER."

"P.S.—If the correspondent's view lenses have their apertures, or rather diameters and foci, in the same proportion, he would probably get the best result out of any given pair by separating them at a distance equal to the sum of their diameters, and then by placing the stop in a position proportionate to those diameters between the lenses.

A PORTRAIT DEVELOPER.

IN a recent number of *La Moniteur de la Photographie* M. Flament gives the details of a developer with which he tells us he has succeeded in producing very fine portraits. He says:—

"Having lately had occasion to take a series of portraits of friends, I made use of an iron developer which has given me several negatives of great beauty. The solution is nothing very particular, but it yields such good results that I cannot help thinking amateurs will be glad to know of the formula, especially as the solution is one which may be kept some days in good condition, a convenience to others, like myself, who are not working every day.

"Developers redden a short time after preparation, and when in contact with the air become charged with acetic acid, to the detriment of their reducing action. To prevent this inconvenience, and in order still to be able to make use of the bath, which in this condition acts rather slowly, I deem it well not to add the acetic acid and alcohol until I make use of the solution.

"I keep a stock of a saturated solution of double proto-sulphate of iron (this salt is soluble, cold, in twice its weight of water), and to twenty cubic centimetres of the solution I add—

Pure or rain water...	80 cubic cents.
Acetic acid	10 "
Alcohol	5 "

The developer in this condition is ready for use. At the same time I deem it well to add, just before the solution is applied to the film, a few drops of a solution of acetate of soda of five per cent. strength, which I have reason to think improves the delicacy of the cliché. The acetate of soda does not, however, in any way accelerate the action of the developer."

FRENCH CORRESPONDENCE.

M. FLAMENT'S MODE OF DEVELOPMENT—HIS MANNER OF PREPARING AND USING DEVELOPING SOLUTIONS—BOIVIN ON ALKALINE DEVELOPMENT—SUBSTITUTION OF GLUCOSIDE OF AMMONIUM FOR CARBONATE—A NEW COMPOSITION FOR MOULDING COMPOSED OF GELATINE AND PLASTER—ACTION OF LIGHT ON HYDRO-IODIC ACID—PHOTOGRAPHIC ARRANGEMENTS IN THE FRENCH MUSEUMS.

To any one who pays attention to photographic manipulation, it is evident that the smallest details have a relatively considerable influence upon the success of the operation. The same formula employed in two cases will not give identical results if, for instance, the work is carried on at different temperatures, or the mode of manipulation is varied in a slight degree. A photographer to whom we owe already many interesting practical details, M. Flament, has lately called my attention to a mode of preparing the iron developer which gives him, in the practice of portraiture, results of a very remarkable character. And yet M. Flament has in no way altered the formula which he ordinarily makes use of; he has only observed, as many others before him, that his solution became reddened a short time after its preparation, and that it also became charged with acid on exposure to air, thus losing much of its reducing action. This fact being proved, M. Flament conceived the idea that it would be advantageous not to add the acetic acid and alcohol except at the moment of employing the developer. The experience of several months has proved that he has done well in carrying out this idea. Here is the manner in which he operates:—He keeps in stock a saturated solution of protosulphate of iron; this salt is soluble, when cold, in double its weight of water. At the moment of developing he takes twenty cubic centimetres of this solution, and adds to it—

Rain water...	60 cub. cents.
Acetic acid	10 "
Alcohol at 40°	5 "

The developer is now ready for use, but before it is poured upon the plate M. Flament adds some drops of a solution of five per cent. strength of acetate of soda, which gives more delicacy and detail to the image, without, however, accelerating the development.

I have at this moment in my hands a very exhaustive communication from M. Boivin on alkaline development. The ingenious experimentalist has pointed out in this note the role which bromide plays as a moderator. As to the pure ammonia, carbonate of ammonia, lime and potash compounds, my friend advantageously replaced them by a substance which he calls by the name of glucoside of ammonium, and which he prepares in the manner following: In 100 cubic centimetres of liquid ammonia are dissolved 10 grammes of glucose (grape sugar); this solution is allowed to remain for some days, and it is then filtered, after which are added 100 cubic centimetres of water. Another filtration of the liquid then takes place, and the liquid is then preserved in a well stoppered bottle. In this way the solution may be kept without undergoing decomposition. The glucoside of ammonium is employed in precisely the same manner in alkaline development as ammonia; that is to say, a few drops of it are poured into the developer at the moment of flooding the plate with the latter. In this way much more intensity, vigour, and uniformity in the development of the image result than is the case with the substances above mentioned.

It is possible also to employ the glucoside of ammonium as an intensifier, with ammonia as the reducing agent; in this case it is applied as soon as the details have appeared. It is well to add, under these circumstances, a few drops of bromide solution, the bromide of ammonium being that preferred by M. Boivin.

I have just seen at the residence of M. Guilleminot some novelties which seem to me of a most successful nature, since they well fulfil the purpose for which they have been

designed. They were accessories for the portrait photographer, and represented artistic furniture, roots of trees, rocks, balustrades, &c., all manufactured with a composition of gelatine and plaster backed with wood. This mixture, which is admirably suited for moulding, takes all the forms which it is desired to give it, even when fine work, or carving upon a piece of furniture, is to be represented. It hardens to a very high degree, and yet it is not heavier than cardboard. It may be coloured and varnished without difficulty, so that it is perfectly suited for anything like theatrical decoration. Finally, it is very inexpensive, so that accessories of this description are very cheaply produced. It is a capital discovery that M. Guilleminot has made, in my opinion, and I believe most photographers will be of the same way of thinking.

In an important memoir on the action of light upon hydro-iodic acid presented last week to the Academy of Sciences, by M. Lemoine, there is this curious fact alluded to. If a certain quantity of this acid is exposed to light for a month in the form of gas, it is found that eighty hundredths of it are decomposed; whereas if the same were subjected to heat during the same time, even to a temperature of 265° Centigrade, only two-hundredths of the gas are decomposed. The action of the light is *nil*, on the contrary, upon a concentrated or dilute solution of the acid in water. The influence of oxygen contained in the air is felt but very slowly.

There is much activity just now in organizing in all the Museums, under the direction of the Minister of Instruction and the National Library, photographic arrangements for the reproduction of objects therein contained by means of the camera. Your readers are already acquainted with the nature of the arrangements that have been made by the French Government for the reproduction by any one, who fulfils the conditions laid down, of the art and science treasures of the State. I need scarcely say that this privilege has been received on all sides with marks of universal satisfaction.

ERNEST LACAN.

ON THE DEPTH OF PRINTS AND INTENSITY OF NEGATIVES.

BY CAPTAIN ABNEY, R.E., F.R.S.*

THE part of the subject which deals with the intensity of negatives is more difficult than that which deals with the depth of prints, as so much depends on the colour of the deposit in the former, and the absorptive qualities of sensitive salt of silver. It may be laid down, however, that the errors in gradation of the former counterbalance, in a great measure, the errors in gradation of the latter, as the errors lie rather in opposite directions. In using the revolving wheel, as in the other experiments, there is a slight danger of error, owing to the scattering of rays by the particles, and their subsequent reflection from the back of the plate; and if this apparatus be employed it is safer to employ a wheel which, instead of giving a gradual increase of exposure from the centre, gives a step by step increase of exposure. Thus, supposing the radius of the wheel to be eleven inches, it is better that the whole of the first inch should give no exposure, the whole of the second inch an exposure of one, of the third inch of two, and so on. By this means, if the density of the middle of each inch of exposure be measured, the error caused by irradiation is practically eliminated. That this is no needless precaution can be proved by the fact that at the outer rim of the wheel, where the spokes are connected together, a sensible deposit will be found on development, whilst nearer the centre, where the exposure commences, the plate will appear perfectly transparent. By calculation, the effect due to the irradiation may be deducted, but the method indicated answers the purpose better.

Again, in settling the part which the density of a nega-

tive plays in protecting sensitive paper, it is almost essential that a modified method should be adopted in order to estimate the results correctly. Suppose we have a large surface uniformly exposed to light, developed, and fixed, and cut such a plate into portions, and place one portion above another, it would be manifestly incorrect to say, without experiment, that the light passing through two of these superimposed portions bore a definitely fixed proportion to that passing through one. In the first place it would be necessary to examine the spectrum of light passing through one, two, three, &c., thicknesses, and to prove that the actinic radiations were uniformly absorbed; and supposing that this was proved to be the case, it would be further necessary to estimate the amount absorbed by each layer.

With an ordinary wet plate negative of a black tint the absorption of light by each layer may be taken to be uniformly carried on through the whole of the spectrum; but in negatives produced by certain dry plate processes (the bath and also the emulsion processes) this is not the case, and, therefore, the modifications indicated in the measurement of such negatives are essential. It is well known that with certain processes a very thin negative is capable of giving a very brilliant print, whilst the same gradation of opacity in an ordinary wet plate negative would give a print decidedly inferior, and wanting in depth if the high lights have to be preserved pure in tone. In estimating the value of the opacity of a negative for experimental purposes it is necessary to estimate the amount of grain in the deposit. Looking at a wet plate under the microscope it will be found that opacity is given by perfectly black particles of metallic silver, which absolutely cut off a portion of the light, whilst the portion which penetrates filters, as it were, through the interstices. On the other hand, in a thin negative which yields a good print, the silver is apparently continuous, and is in an excessively thin layer. In this case it appears that the grain is much finer, and the interstices smaller, than with an ordinary wet plate; and that the light, which is transmitted through the metallic silver itself, together with that filtering round it, is less than it would be were the particles opaque, or arranged in coarser manner.

Again, it must not be forgotten that in some processes, the salts of silver are reduced to the metallic state in the thickness of the film itself, and not simply deposited on the surface, as in the case of wet plates—more particularly when using horny collodions.

The accompanying figure shows in a marked manner the

Fig. 13.

difference in gradation that is to be observed in two negatives produced by different processes. The curves are from prints taken on a three per cent. paper, printed from negatives exposed under the rotating wheel, and, as before stated, a certain allowance must be made for irradiation, though in the corrected curves the general effect would not be greatly different. A is the curve obtained from a wet plate negative, and B that obtained from an albumen beer plate negative, developed solely by the alkaline method. The colour of the former deposit is of the well-known grey-black, and of the latter of an olive-green tint.

From these there is instruction to be got. It will be

seen that the wet plate negative gives too rapid a gradation in those parts where the dry plate gives too slow a gradation. By combining a wet plate development with the alkaline development, the gradation should prove more nearly correct; the curve given by such a method lying more nearly in the line indicated by C. This is nearly obtained by employing the alkaline developer to bring out a faint image, and then intensifying with pyrogallie acid and silver. Some operators have found an increased delicacy in a negative so treated, and this may account for the fact. Be this as it may, it seems that there is evidently much to be considered in the way that a negative is treated. It should be noted that the wet plate negative was developed with a fifteen-grain ferrousulphate developer, and the dry plate with strong alkaline development, as given in my paper that appeared in the News in January last. It must be distinctly understood that the above diagram only gives types of a certain class of negatives, and that only for a portion of the intensities (though they are of such gradation as would yield vigorous prints when toned and fixed); and also that any alteration in the strength of developer and modes of development, &c., modify the resulting prints. On a future occasion it may be deemed desirable to treat of these.

PHOTOGRAPHY IN AMERICA.

BY NORMAN MAY.*

As compensation, in some measure, for the low salaries, the assistant finds the American photographer, as a rule, much more hospitable and kindly disposed towards him. He can make pretty sure that he won't be treated with a frown, and almost ordered off the place, if he should happen to call in search of a situation; but should no vacancy occur in that establishment, he will be recommended, with good wishes, to any friend or photographer whom they think likely to require any one. There seems to me a greater amount of sympathy and good-will, not only between employers and employed, but among employers themselves. An American will always be pleased to show a brother photographer, though a stranger, over his studio, and explain to him the working of anything that he may think useful. A great many English photographers would think the man very intrusive, and perhaps impudent, who would express a wish to look over their studios, and would be careful to keep out of sight any little dodges they thought helpful to make their pictures better than their neighbour's, and they go on in their own conservative fashion, rarely giving or taking a hint from any one. Can such men hope to excel? Some possess the finest instruments, get the best of chemicals, and use them with great intelligence; but still cannot and do not keep pace with the rapid advance of photography, but go on in the same old groove, till, on being shown some work of superior excellence, they see how immeasurably they have fallen behind. Even then their awaking is but of short duration, and after a little spurt or two they sink to their ordinary level. What reader cannot call to mind such a case as this?

The American exhibitions and associations are deservedly popular, and do an immense amount of good in educating and elevating the photographer, to say nothing of often taking the conceit out of him. A photographer who is "cock o' the walk" in his own immediate neighbourhood is flattered, and made to think he is a little king in the art, by his friends, and he is persuaded to send a frame or two to the exhibition, firmly believing that he is going to show them something extraordinary. He follows in a week or two himself, and sees how utterly insignificant his productions are compared with the pictures of others of whom, perhaps, he has not even heard. He goes home a wiser, if not a sadder man, finds out in which

* Continued from page 391.

direction he can improve, and by the next year he has made great progress; and though he knows there will be better photographs than his exhibited, yet he fondly hopes he will be able to stand the comparison better this time, and is amply rewarded by the encouraging remarks of his brothers in art. During the week of the Convention in connection with the National Photographic Association, photographers meet and discuss the latest improvements. Old ideas will come up with new faces, photographs are exchanged, useful acquaintances made, lectures given illustrated with the lantern or dissolving view apparatus, and, altogether, the photographer feels he has not made the journey of often one thousand or more miles in vain.

Their exhibitions and meetings are almost invariably a great success. Somehow, they seem to infuse more life and spirit into them than the English generally do, and more real and permanent good seems to be done. Each individual member thinks he must do what he can for the general good, and they go into it with right good will, determined to succeed, and, therefore, rarely failing. I attribute the success of the Americans, in a great measure, to their good feeling towards each other, their willingness to explain and show what they find of benefit to themselves, their exchange of ideas, and study and criticism of each other's works; in short, the absence of that conservatism that exists to a vast extent among English photographers.

Though the Americans are a most hospitable and genial people, they do not neglect a chance to make the almighty dollar, and advertising finds much favour with them, sometimes in the most original and ingenious way. In the suburbs of a town—or, indeed, in the town, if there is a vacancy—the side-walks and fences, especially, are covered with phrases extolling the beauties of "So-and-So's" articles. I have seen many curious advertisements on the board fences, but never expecting to write of them, and seeing so many of all businesses, I did not take any notice of them; but "So-and-So is lightning on children, and 'old folks, too!" would rather astonish and amuse English people. "So-and-So is a whale on Rembrandts!" would also sound at least peculiar; yet such are genuine advertisements. "Cleanliness is next to Godliness. Buy Morgan's soap!" was painted on the stables adjoining a church. Very suitable and appropriate, perhaps, but rather different to what we are used to, and what we should consider the thing. Still the Americans are quite a different people to the English, and have different ways of doing things. Their own way is much more conducive to their success, seeing the people and materials they have to deal with, than the English one would be.

The Editor of the *Practical Photographer* was quite right when, alluding to the criticism of the English writer in one of the photographic journals a few weeks since, he said that the American's expressions were "not understood" in England, and, therefore, often condemned, as people often laugh and sneer at what they do not understand. An Englishman finds himself in just the same circumstances when he goes to America; and till he gets used to and understands the people, it's hopeless for him to think of succeeding in any commercial enterprise. That editor knows the people he is writing for, and cannot be taught by an Englishman how he ought to address them.

Respecting the good feeling among photographers, I once called on a photographer in Clinton, Iowa, an utter stranger to me, who, without any letters of introduction, invited me to stay at his house for a fortnight or so, and would hardly take a refusal. I dined with him once or twice, and shall not soon forget his kindness. I have heard from him since, and he sent me photos. of himself, wife, and daughter, which for retouching and general excellence are not at all behind the work of some of our leading men, and that from a little town of five thousand or so of inhabitants, possessing four or five other photographers. Of course, every one won't invite a stranger to stay a few weeks, but such an incident as I have men-

tioned would hardly be possible in England. Among no class of men have I seen a greater amount of good feeling than the photographers of America, a trait which the English might copy with advantage, instead of being afraid every one that calls on them is going to learn their secrets, and use them to their disadvantage. How long will it take people to understand that it is not the apparatus or formula that makes the picture?

(To be continued.)

THE LEAD INTENSIFYING PROCESS.

BY DR. V. WARTHA, OF PESTH.*

DR. EDER has asserted that the action of nitrate of lead and ferri-cyanide of potassium upon silver forms ferrocyanide of silver and ferrocyanide of lead, and further states that the reaction proceeds as under:—

I believe that, supported by my former experiments, I shall be able to prove that these decomposition equations are not exactly correct. At the same time I desire to make a few general remarks upon the subject of the lead intensifying process.

Although it is a very generally-known fact, still it is worth while to call attention to the circumstance, that the lead intensifying process can only be undertaken in the dark, the progress of the action being watched from time to time by the aid of diffused light†. If this precaution is not taken, then, in consequence of the separation of ferrocyanide of lead by the reduction of the ferri-cyanide of potassium, a white precipitate is formed, which very often gives rise to fogging of the negative. Everyone who has worked with a lead intensifier may not have remarked this white precipitate, but instead, a yellow one; in the same way it will be found that the action of very fine silver leaf upon a solution of ferri-cyanide of lead is followed, not by a white precipitate, but by an orange-coloured one. If, further, the lead intensified plate is covered with water which contains but a minute quantity of hyposulphite of soda, then a yellow turbidity is produced, and the plate becomes white. The orange-coloured precipitate which appears in solutions of ferri-cyanide of lead is only reduced by the addition of an excess of silver leaf; and, in like manner, the orange plate is completely discoloured when put into water containing fine zinc particles in suspension. We have here to do with a reduction process, and the ferri-cyanide of silver which has been formed is reduced.

The colour of the precipitate, and its reducing property through zinc and hyposulphite of soda, point to its containing ferri-cyanide of silver, and I believe that the under-mentioned equations properly express the matter:—

Or, in other words, there is formed a ferri-cyanide compound, and not one of ferrocyanide.

If silver acts alone upon ferri-cyanide of potassium, only white ferrocyanide of silver is formed, and, so far, is the observation of Dr. Eder perfectly right; if, however, nitrate of lead comes into the question, then the matter is different, and the solution behaves as if it were a solution of ferri-cyanide of lead.

Finally, I may remark that I have not been able to succeed in intensifying dry plates by the lead process. Most curiously, the precipitate which is formed permits itself to be washed off like loose sand, and this, I think, may be explained by the fact that, in dry plates, the silver image lies upon the surface of the collodion film, which, in the case of wet films, is in the body of the collodion itself.

* *Photographische Correspondenz*.
† Dr. Vogel contradicts this assertion.

Correspondence.

YELLOW GLASS FOR SPECTACLES.

DEAR SIR,—Seeing an article in the News of August 10th concerning yellow light, and a suggestion as to the use of yellow glass for spectacles, I beg to inform you that I have found it to be a fact that yellow glass gives greater rest to the eyes than either blue or green glass. I have ascertained this fact for the last three or four years, having been in the habit of holding a piece of yellow glass between my eyes and my book when reading; I also found that I could see objects at a distance much plainer with it than without it. Acting on this I made myself a pair of spectacles by chipping a couple of pieces till near the size of an old pair of rims which I had by me, then I rubbed them on a stone until they fitted properly. I found they were very useful, but they ought to have been made of a larger size. To prove their efficacy I took them with me one day when visiting my brother, who is a member of the Merthyr Volunteer Force, and he proposed we should go to the targets, as it was practice day, and try their use. The drill sergeant, who was present, and several volunteers who were there, all said it was the best thing for the eyes they had ever tried, as it took off all the glare of the light without impeding vision, and allowed them to see the targets most distinctly.

If you think this worth publishing, it is at your service for the purpose.—Yours truly,
J. L. BUNAY.
1, Market Street, Aberdare, South Wales, August 14th.

Proceedings of Societies.

EDINBURGH PHOTOGRAPHIC SOCIETY.

One of the ordinary out-door meetings of this Society was held on Thursday, the 9th inst., the locality selected on this occasion being Aberdour, one of the most picturesque places on the banks of the Forth. The village itself—a favourite watering place with a quaint old harbour—is flanked both on the east and west with such beautiful combinations of rocks, wood, and water, as to have long made it a favourite resort of artists, both of the brush and the camera.

The boat, the *Lord Aberdour*, was timed to start at 9.30, by which time the members were on board in the exuberant spirits usual on such occasions when the appearance of the day promises to be favourable to good work, but they were doomed shortly to be damped, in more senses than one. Although the atmosphere was bright and clear when they started, before they had got out of the harbour they were enveloped in one of the dense fogs that occasionally comes on, making it impossible to see from one end of the vessel to the other, and condensing in minute globules, like hoar frost, on the dresses and beards of the passengers. Under such circumstances progress was, of course, slow, and the almost incessant sounding of the fog whistle, answered occasionally by the faint twinkle of the bells of the vessels in the offing, had a peculiarly weird effect, not at all unpleasant, but certainly not pleasant enough to make up for the disappointment likely to be caused by the failure of photographic operations. Happily, however, it proved to be of but short duration, and when within sight of Aberdour it disappeared as suddenly as it came, revealing a brilliant sun in an almost cloudless sky, and with an atmosphere so still that not a leaf was stirred.

The road from the landing pier winds round the face of the Hawk-craig, and at every turn offers some new and charming bits for the camera; but the party pushed on to the harbour, where, in consequence of the tide being sufficiently out, several vessels were grounded, and a number of exposures were made on most picturesque combinations. The Castle, Hawk-craig, and the woods to the east, offered some tempting pictures, but it was decided to reserve them for a future excursion, and work westward instead, and therefore the party passed through the village, and lunched in the pretty hotel immediately opposite the gate and entrance to the Donibristle grounds. After luncheon an ordinary meeting was constituted, with Dr. JOHN NICOL in the chair, and some routine business transacted, including the admission of Messrs W. Bertram and James Robertson as ordinary members.

The drive through the Donibristle grounds is enchantingly beautiful. Wooded almost to the water's edge, the cathedral-aisle-like avenues offer here and there most lovely peeps of Inchcolm, Cramond, and other islands which stud the Forth, and give a variety of which the visitor never tires. The first halt was made at Dalgety Church, a fine old ruin, built in the fourteenth century, and in which lie the remains of many of the Seton family. It stands in a beautiful bay, close to the water's edge, and although requiring very wide-angle lenses, affords several fine pictures. Here the cameras were set up, and as long exposures were required they were left to look after themselves while some of their owners enjoyed a refreshing swim in the Forth, and others, under the leadership of Mr. Sinclair, extemporised a choir, and gave full vent to such music as the surroundings always inspire. From Dalgety the drive was continued to Donibristle House. Donibristle, like most houses of its time, has seen many ups and downs. It was at one period the residence of the abbots of Inchcolm, and has been three times destroyed by fire, the last time only some dozen years ago. It consists of a centre and two wings, the latter at a considerable distance from the former, and connected with it by under-ground passages. The centre is a mere shell of crumbling walls, but the wings are still inhabitable.

The only thing of interest here—at least, of interest to the photographer—is a fine example of forged work, in the shape of a gate presented by Queen Anne of Denmark. This was photographed from various points, and after enjoying the "soft recumbency of outstretched limbs" on the velvety lawn which dips into the water, the drive was continued across the grounds, and out by the north gate.

Fordel Castle, with its exquisitely beautiful garden, was the next object of attention. Under the guidance of Mr. Foulis, who has been for nearly fifty years at once head gardener, factor, and general factotum to the Hendersons of Fordel, the party were first conducted through the extensive garden and "houses," and then through the beautiful glen that leads to the castle, an ancient baronial relic of former times. It is in excellent preservation, and contains many curiosities, including some large pieces of tapestry from the old home of Pitreavie. The glory of the place, however, is the ornamental garden, which it would be difficult adequately to describe, and on which the highest possible degree of gardening skill, guided by the purest taste, has been expended.

The remaining plates were exposed here, and the rest of the time spent in examining the castle, and listening to the lore connected therewith, so humorously retailed by our guide, until they were obliged to leave in order to catch the last boat, which they did after a hurried tea in the hotel, and arrived safely in Edinburgh about nine o'clock. We may add that all the plates used were the collodio-bromide emulsion, and that the exposures varied from five to forty minutes.

AMATEUR PHOTOGRAPHIC ASSOCIATION.

A COUNCIL meeting of the Amateur Photographic Association was held July 31st, T. SORWICK, Esq., M.A., F.R.S., &c., in the chair.

The minutes of the last meeting having been read and confirmed, H. B. Broadhurst, Esq., and the Rev. W. E. Hancock, were elected members.

The SECRETARY called the attention of the meeting to the fact that a large number of old prize negatives, which are the property of the council, were now rarely used for printing purposes; and suggested that it might be well to present them to their previous owners.

After a long discussion, it was proposed by Mr. Glaisher, and decided by the meeting, that, as the question was one of considerable importance, it should be postponed for further consideration at the next meeting of council. A. J. MELHUIS, Hon. Sec.

Talk in the Studio.

BOUCH'S NEW CATALOGUE.—The catalogue just issued by Messrs W. W. Bouch and Co. ought to be in the possession of every photographer. It is not simply a very complete list of apparatus, chemicals, and other photographic material, but, in many respects, a valuable handy reference-book containing much information and many hints in practice. The illustrated descriptions of much of the apparatus will also be found valuable and interesting.

PRETENDING TO TAKE PHOTOGRAPHS.—A novel crime in connection with photography is mentioned in a Worcestershire

paper William Stewart, described as a travelling photographer, is said to have been sentenced to twenty-one days' imprisonment for fraudulently obtaining moneys from school children, whose photographs he pretended to take with a blacking box. A similar fraud was perpetrated, a correspondent states, some years ago, when a travelling photographer "hard up" used a plate box with a flange screwed on, as his pretended camera.

To Correspondents.

B. C. A.—Non-members, as well as members, are eligible as exhibitors at the forthcoming Exhibition of the Photographic Society; and are also eligible as competitors for the prizes offered. The conditions of membership in the Society are an interest in the art and the compliance with the rules of membership. To become a member you must be duly proposed by a member. The nomination having been submitted to the Council and passed, the nominee is then submitted to the ballot in a meeting of the members, and elected. The subscription is one guinea annually, and one guinea entrance fee. We regret that extreme pressure of duty did not permit us to write. We shall have pleasure in proposing you as a member of the Society if you desire it. The next session commences in November next.

A. CONTINENTAL SCHNITZER.—It is not an easy task to criticize a series of views, and say how far they conform to the canons of pictorial composition, nor is it a pleasant task to point out individual shortcomings, but it should be candidly done if we are to be of service. There is in the pictures forwarded a general tendency to under-exposure, which is very injurious to landscape photography, as it tends not only to produce harsh contrasts of black and white without detail, but also to destroy all atmospheric effect. In No. 1 the wall in front of the cottage is a mass of black with-out detail, quite antagonistic to pictorial effect. No. 2 is better as regards exposure, but there has been a diffused light fatal to detail, and to light and shade, especially in the building at the right hand of the picture. There is, moreover, in the foreground a mass of road without any object of interest to break its unpicturesque monotony. No. 3 has more pictorial quality, and has a slight tendency to over-exposure. No. 4 is under-exposed; the foreground is an unrelieved black mass. No. 5 is better but there is no detail in the masses of black-looking foliage. In No. 6 the point of view is faulty. The spreading mass of water which forms the foreground, with a narrow strip of landscape high up in the picture, form a very unsatisfactory picture. No. 7 is under-exposed, and has not detail in the uninteresting foreground, nor in the foliage. Nos. 8 and 9 are spoiled artistically by the unpicturesque character of the foreground lines of railway are rarely picturesque, and especially if constituting the most prominent elements of the picture. If suitable cloud negatives had been printed in the sky, the pictorial effect would, in many cases, have been somewhat redeemed, but a black sky is fatal to even very good landscapes. The omission to which you refer in the *Jahrbuch* is curious, but will probably be rectified next year.

R. O. L.—The defect known as "crapshoot," of which you complain, is due to the presence of too much water in your collodion, or, in other words, to the use of ether and alcohol insufficiently rectified. It is probable that excess of somewhat weak alcohol has been used. Equal parts of ether, of a sp. gr. of .720, and of methylated spirit, sp. gr. .820, will generally give a satisfactory collodion; but if, as you say, you have used two parts of rectified spirits and one part of ether, the collodion will probably contain too much water. The collodion once made, you cannot remove the water, but you may use up the collodion by mixing it with another good sample. You may also, to some extent, modify the defect by letting the film set well before immersion in the nitrate bath.

F. L. D.—For use on opal glass, collodio-chloride of silver should always have citric acid added. In printing with this preparation on opal glass we prefer to work on the glass itself without any substratum. Take dilute albumen, consisting of one part of white of egg to three or four parts of water, and apply an edging about one-eighth of an inch wide all round the glass; when that is dry, coat with collodio-chloride. Allow the film to set thoroughly. Then dry by a dull fire, and print as soon as the film is cold again. Tone in an old weak gold bath. Fix by immersion in a hypo bath, containing one part in eight, for five minutes; then wash under a tap for five or ten minutes. Plates so treated will be quite permanent. There are two causes for films splitting: one is the use of a very tough contractile collodion, the other the use of a collodio-chloride which has become somewhat decomposed with age.

R. H. P.—The method of preparing and using Lohmann's salt for producing red negatives has been more than once described in our pages. You would not be able to procure the salt ready prepared. It is a troublesome method of intensifying, and of doubtful value, as the deposit is not certainly permanent.

B. W.—The case is doubtless a deplorable one, and, we fear, only too common.

PERPLEXED.—You have thrown down all the silver in your bath as carbonate, which may be converted into nitrate by means of nitric acid. The idea that you must add the soda solution until there is no more effervescence is altogether an error, as there will be constant effervescence on adding it until all the silver is precipitated as a carbonate. The proper plan is very simple. Make a ten-grain solution of bicarbonate of soda, and keep it for use. Add of this a few drops at a time, shaking the bottle containing the silver solution, and then allowing it to stand a few minutes. Continue the addition until there is, after standing, a slight permanent turbidity, which will show that all the free acid has been neutralized, and a trace of the nitrate has been converted into carbonate of silver. Now place the solution in the sun for a few hours—or, if possible, a few days—then filter, and try a plate. It is probable that the bath will work clean and bright at once; if not, add a slight trace of dilute nitric acid.

S. J. B.—We fear that we have no means of helping you. The case is certainly very annoying and perplexing, but at the same time difficult to remedy. The plan you propose could not with safety be adopted. Your best plan will be to secure the aid of a solicitor; possibly a letter from a solicitor might be effectual.

J. L. HANLEY.—Send to our publisher a copy of each print, with full details of title of picture, name of photographer, name of proprietor of copy, &c., with 1s. 6d. for each picture, and he will get the registration effected for you.

RAWHAKAANA (N.Z.).—Your account of your trouble is too brief. Transparent spots are of many kinds, the most common being known as pinholes. Their causes are various, and have been much discussed of late in our pages. One of the most common causes is excess of iodide of silver in the bath. To remove this pour the silver solution into double its bulk of distilled water, and then filter and make up the proper strength by adding nitrate of silver. The addition of two or three grains of nitrate of baryta to each ounce of solution sometimes proves a remedy.

J. W.—Your bath, which has been used for paper, cannot with safety be used for collodion plates, but if you get unsensitized paper you can then use your bath. You had better now use the gold for the formulae for which you have prepared it. Let us know from time to time how you get on, and do not fear to state all your difficulties.

Several Correspondents in our next.

METEOROLOGICAL REPORT FOR JUNE.

BY WILLIAM HENRY WATSON, F.R.S., F.M.S.

Observations taken at Brighton, near Whitehaven, 26 feet above sea-level.

Date.	Barometrical Pressure.			Temperature in the Shade.			Remarks.
	Morning.	Noon.	Night.	Morning.	Noon.	Night.	
1	29.80	29.85	29.83	62°	64°	60°	Fair and sunny
2	29.80	29.70	29.73	56	61	56	Fair, but gloomy
3	29.77	29.73	29.77	56	58	54.5	Heavy showers of rain, with hail, this morn and afternoon
4	29.80	29.70	29.60	58.5	61	57	Fair and sunny
5	29.80	29.70	29.71	57	61	55	Fair and sunny
6	29.84	29.70	29.63	53	59	51	Heavy showers, with distant thunder,
7	29.83	29.60	29.60	50.5	61	53	showers p.m. (this evening)
8	29.80	29.61	29.60	54	58	54	Fair, but gloomy
9	29.77	29.60	29.62	56	59	56	Rain nearly all day
10	29.74	29.43	29.43	52.5	54	50	Rain p.m.
11	29.80	29.67	—	51	52	54	Fair, generally cloudy
12	29.75	29.70	29.70	61	62	59	Fair, generally bright
13	29.75	29.60	29.60	61	62	59	Rain a.m. and p.m.
14	29.70	29.16	29.02	61.5	60	61.5	Rain a.m. and p.m.
15	29.70	29.60	29.60	63	60	58	Rain a.m. and p.m. Heavy clouds
16	29.60	29.67	29.16	57.5	60.5	56	Rain a.m. and p.m.
17	29.70	29.60	29.40	56	62	58	Rain a.m. and p.m. Very heavy
18	29.70	29.60	29.72	56	64	53	Fair and sunny
19	29.70	29.54	29.61	63	60	56.5	Rain this afternoon and evening
20	29.70	29.70	29.60	53	60	56	Fair, generally sunny
21	29.70	29.60	29.60	—	61	60	Rain a.m. and p.m. Thunder and light-
22	29.70	29.60	29.60	60	61	61	Rain a.m. and p.m. (ang at night)
23	29.70	29.60	29.60	62	64	59	Rain a.m. and p.m.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

**CARBON PRINTING IS THE PAST—DESTRUCTIVE HAILSTORMS—
—ARE FUMES AND VAPOURS PREJUDICIAL TO PHOTOGRAPHIC WORK?**

Carbon Printing in the Past.—Carbon printing is still talked about with such an air of novelty at the present day that one is apt to lose sight of the fact that ten years ago it was being practised on an immense scale by one firm at least on the Continent. Probably the most extensive photographic establishment in the world, that of M. Braun of Dornach, employed pigmented tissue in the production of photographic prints immediately after the process was practically demonstrated by Swan of Newcastle, and we remember well, when we visited the vast institution in 1870, the work had already been going on on a large scale for a couple of years. It seems, therefore, a little singular to be still talking at the present day about the introduction of carbon printing into our studios in this country. No doubt in Braun's establishment there were many things which contributed to the success of carbon printing when it was once adopted. In the first place, the establishment of M. Braun is probably the largest and most complete photographic studio in the world, and thus help and assistance are always at hand whenever needed, no matter whether the same be required from the chemist, the practical photographer, the artist, or the manufacturer. When we mention that in 1870 there were no less than one hundred hands employed at the establishment, from the boys and girls employed on the printing and development of the images to the skilled artists engaged to retouch negative and positive, it will be seen that the resources of the establishment were well-nigh unlimited. The advice we have always given our readers who are engaged in carbon printing, to maintain everything connected with the work at a cool temperature, was a point which was never lost sight of at the Braun institution. A vast deal of cellar room existed at Dornach, and the operating and printing rooms opened out from these cellars, so that liquids and utensils are always preserved at a cool and uniform temperature. Well-nigh everything connected with photography was prepared on the premises; not only was the pigmented felsche tissue ground, and mixed, and spread upon paper in dry, sensitive condition ready for printing, but the chemicals—such as collodion, chloride of gold, nitrate of silver, &c.—were all made under the superintendence of the principal. No doubt this system contributed in no small degree to the success which characterized the Dornach factory. In those days no difficulty was made about printing pictures one metre and a quarter in length, and to show the extent to which carbon printing was actually resorted to it may be mentioned that from twenty-five to thirty bands of tissue, each measuring twelve feet in length, were daily consumed. We are not aware whether the production of photographs is carried on in the same extensive manner at the present day at Dornach, or by what modification of the process, if any, carbon prints are now secured. It was the Swan method which we saw in operation nearly seven years ago, but since then M. Braun, it is said, has established a house in Paris, and occupied himself with some of the novelties in carbon printing with which our readers are familiar. The Braun firm was wont to take all its own negatives, and made it a rule never to purchase. If pictures of the Nile were desired, or of Swiss glacier scenery, a competent photographer was at once despatched to obtain them, and as many as five gentlemen were constantly employed by M. Braun in travelling here and there in search of the picturesque. In this way the principal was enabled to control every negative, and no doubt this fact had something to do with the uniformity with which they could afterwards be printed. Indeed M. Braun would pride himself on remarking that he has conducted the whole

of the photographic operations from alpha to omega. Since that prosperous time of which we talk, Dornach has changed its nationality, and those who now reside in the Alsatian village are no longer French subjects. We do not know how far this matter has affected the prosperity of this flourishing establishment, but we remember that just before the close of the war M. Braun was called upon by the Prussian Government for a heavy money subsidy to make good the damage done to a German train which had been maliciously damaged by villagers who sympathized with the French. At the close of the war all were permitted to choose whether they would be French or German citizens in the future, and from the fact that a branch, at any rate, of the great Dornach firm has proceeded to Paris, we may infer that at any rate the Dornach establishment is not what it used to be. In any case, however, the name of Braun will always be connected with the early history of carbon printing, for he was the first undoubtedly, after Swan, to employ the process practically on an extensive scale.

Destructive Hailstorms.—Photographers in this country may congratulate themselves that they are not visited by the

destructive hail-storms which appear from time to time to sweep over Continental cities. From Berlin, a short time ago, news came of a most disastrous visitation of this sort, and our German cousins, we see, are earnestly taking up the question whether, under the circumstances it is not advisable to establish a Photographic Glass Insurance Company. As with us, there are at Berlin insurance companies where insurances may be effected against plate glass, but there are no establishments, seemingly, where ordinary glass may be insured. According to statistics which have been collected, no less than a score of photographers suffered loss by breakage by a late storm, the damage done in some instances being very great. One firm, it appears, had no less than 700 small panes broken, and another 225, testifying very vividly to the weight of the hailstones, and the terrible character of the tempest. Fifty, seventy, ninety, are the number of panes broken in many of the studios, representing a most serious and unexpected loss, some of the panes being very large and expensive. Toughened glass has been suggested for future use, but its expense, as also the lack of any information as to its being competent to resist sharp and sudden blows such as would be inflicted in a violent storm, naturally lead our brethren to avoid such an expensive substitute. The best way out of the difficulty would be, we should think, to establish a mutual assurance against such accidents, if such an institution could be formed among the photographers of the Vaterland.

Are Fumes and Vapour Prejudicial to Photographic Work?—Some discussion has recently taken place among the members of the Berlin Society for the Advancement of Photography in regard to the alleged destructive action of fumes in the dark room. A Swiss photographer, who had his studio next door to a goldsmith, complained that his plates were very apt to fog, and he attributed the defect to his neighbour's premises, although these were separated by a thick wall. Herr Quiddle, as also Dr. Vogel, were of opinion that too much importance was placed by photographers in general upon the injurious influences of fumes and vapours. Even strong ammonia vapour has no action upon the sensitive plate, at any rate if the silver bath gave an acid reaction. Dr. Quiddle stated that the only time he had noticed that the collodion film suffered was when his laboratory had been freshly white-washed, the odour of the lime acting prejudicially upon a sensitized film. No doubt these gentlemen are right in their dictum, but, for all that, we would advise photographers to keep their room as free as possible from fumes. The latter are, at any rate, not beneficial to the plates, if they do not act prejudicially, while it is very certain that vapours of one kind or another, if harmful to photographs, are not so to photographers. A well-ventilated dark room we hold

CLEANING THE DAGUERRETYPE.

BY W. L. SHONMAKER.*

It certainly is a matter of vain regret that one feels, on removing a Daguerreotype from its case, that a specimen that represents such a wonderful era in the graphic art should be subjected to ruthless handling by many professionals of the present. We have had pictures of every kind brought to us for copying, and I find the Daguerreotype the worst abused of all.

Although I have never followed the art of Daguerreotypy, still I appreciate and admire the wonderful results that often pass through my hands.

A photographer sent us a package consisting of a large number of Daguerreotypes and ambrotypes. These were taken from their cases, their mats, glass, and preservers removed, each wrapped in a little piece of tissue-paper, the whole enclosed in a paper box; when received the ambrotypes were broken to flinders, and I had to practise the mosaic art to repair damages; the Daguerreotypes scratched to destruction.

About three years ago, two frames of Daguerreotypes, each containing about one hundred one-sixth size pictures, were sent to us to clean and replace. These pictures were placed in a velvet matt without sealing; the action of the gases of the atmosphere had obliterated most of the pictures, and they were unrecognizable.

To clean them and replace in the matt would have been easier than any other method, but I desired to make them a permanent thing if I could, and tried the following experiment: first removing, brushing off all loose particles, then immersing in a dish of hot water: this removed all gum from sticking paper on back, and softened the coating on surface quickly, so that on laying in a dish of weak cyanide, they cleaned nicely; after washing well, I poured over the surface raw albumen, gave a slight rinse under a small flow of water, then set up to dry spontaneously. After thorough drying each was placed in a dish of alcohol for a few minutes; this caused the albumen to be made insoluble, or, in other words, cooked it.

If the albumen is moist in the least degree when placed in the alcohol, the surface will dry opaque, and trouble will be given to remove; it but if the surface albumen is thoroughly dry it will remain transparent, and dry spontaneously.

This method I found left a good coating on the surface, and could be rubbed quite hard without marking.

I hesitated making this public at that time, as I desired to wait and see if they returned to their original condition; but on examining them a few weeks since I found them all good yet, no change having taken place. I felt doubtful myself at the time, for all who have cleaned Daguerreotypes, although they may have sealed them properly when putting them up, will know that a picture once cleaned is more liable to change than ever, if not very carefully washed.

RESTORATION OF PRINT BATHS.

BY A. STOCK.†

Now it has been customary to treat silver baths, whether they have been employed for the dipping of plates or sensitizing of paper, in precisely the same way when defective or out of order, notwithstanding the fact that the print bath becomes contaminated with quite a different series of organic compounds and impurities. This should not be, for the latter requires, as a matter of course, special treatment, although, strange to say, no manual gives any definite information on the subject. The ordinary impurities that enter the print bath are gelatine or size, superfluous acid, and combination of the latter with the chloride salts employed in the preparation of the paper. The precipitation of

the gelatine matter, as of the organic compounds, is brought about by the following means:

1. The silver bath is treated with alum solution 1:10 strength (ordinary alum dissolved in hot distilled water), until small crystals are seen to form, when the liquid is filtered. These crystals are silver albuminate, which are dissolved again in hot distilled water, and added to the silver bath again; a portion remains dissolved, while the rest again separates. This silver albuminate may be employed, therefore, again and again.

2. By adding and filtering off again burnt alum or hydrated clay, for, as is well known, the oxyhydrate of aluminium possesses a considerable tendency to combine with organic substances, and precipitate the same when in solution. As the hydrated clay exerts the same action against colour, it is far preferable to permanganate of potash when any discolouring of the bath takes place.

If the print bath is acidified pretty strongly with acetic acid, and the kaolin added until the smell of acetic acid has disappeared, and the whole filtered, then the sizing material is also completely coagulated by the acetate of aluminium which has been produced.

There remain still the different acids and their salts to neutralize and decompose. To do this, carbonate or bicarbonate of soda has hitherto been recommended to be employed. Now, although both those compounds, and especially the latter, are excellent agents for neutralizing the silver bath, I have never found the result to be a marked improvement in the bath.

On the other hand, we possess in caustic potash and soda two excellent means in neutralising and decomposing acids and salts present in the print bath. Both are dissolved in ten parts of distilled water. From one of the two solutions (the first is to be purchased of any chemist) enough is added to bring about a gelatinous precipitate, the liquid being from time to time vigorously shaken. The silver bath now assumes a transparent, milky turbidity, or, if it does not, more caustic potash is added, until the turbidity does not disappear, and litmus paper betrays a neutral reaction. This gelatinous precipitate cannot be filtered off, either by means of bibulous paper or cotton-wool, as all the pores are very soon plugged, and only moistened linen or flannel can be used for the purpose. The linen or flannel is strained tightly upon a square wood frame, and the liquid poured in the middle; the strainer must not touch at the bottom, but remain free. Neither must it be pressed, as in that case some of the gelatinous precipitate is forced through. It is well to let the filter process go on during the night, and then there is plenty of time for the liquid to run through bright and clear. Those who are not conversant with this method of filtering or straining should be initiated into it by a chemist. After the operation the cloth may be dried, and be employed again. In adding various substances to the print bath in order to purify it, one need not be nervous about going to work, for there is no harm in being a little out, and the print bath does not require such delicate handling as is the case with the negative bath.

Print baths treated in the manner described will be found to possess all the properties necessary to good working, and to impart to albumenized papers the finest lights and shadows. At the same time, the restoration of a print bath should not be delayed for any length of time, as sometimes happens with the negative bath, but should be treated periodically, especially so far as neutralization with caustic potash is concerned. If the bath becomes too alkaline, it may easily be rendered neutral again, after straining, by the careful addition, drop by drop, of pure nitric acid.

In the above lines I have desired to indicate the theory involved in the proper restoration of the print bath, and thus to acquaint my friends with the why and wherefore of the reactions.

Dr. Liesegang, in connection with the subject, points out the method employed by Mr. Maxwell Lyte to purify a turbid, brown print bath, a method which Dr. Liesegang

to be one of the essentials towards clean manipulation, as it is certainly the only means whereby photography can be persistently practised without, in some way or other, being prejudicial to health.

GERMAN CORRESPONDENCE.

PHOTO-GRAYURE AND PHOTO-CHROMY—PERMANENCY OF CARBON PICTURES ON GLASS—INTENSITY OF ELECTRICAL LIGHT—CARBON PRINTING PROCESS IN SUMMER—WAR AND PHOTOGRAPHY—HOW MANY PHOTOGRAPHERS ARE IN THE WORLD?—QUANTITY OF CHEMICALS THEY CONSUME.

BY DR. VOGEL.

LAST year I sent you some information about Goupil's process of photo-gravure, which originally was invented by Woodbury. Recently there was brought into the market a series of printed leaves, prepared by this process, of which some have a size of twenty-two inches, and which, in general, meet with an acknowledgment among artists. In beauty they are equal to the old scriptum, and, indeed, they may be considered the most perfect invention so far in the line of photographic copper-plate printing. Goupil has also brought into the market coloured prints of this kind, the effect of which is considerably increased by their harmonious colours. About the other French process, photo-chromy, I must speak less favourably. The products of the same are sent to Germany in large quantities, and M. Vidal did not hesitate to produce in photo-chromy the portrait of the greatest enemy of France, our Emperor William. But the picture looks as if Vidal intended to take revenge in a photo-chromical way for the political defeat of his native country. As a basis he made use of a photograph by Loescher and Petzsch. The colour work of this picture is done in photo-chromy; but it appears as unnatural as possible, and it is the plainest proof that the assertion *Photography en couleurs naturelles* is only humbug.

The pictures of objects of mechanic arts, produced in the same way, are prettier. In many cases they can be done in a very simple manner by means of the carbon printing process. M. Prumm, of this city, has made a picture of a fine sword, gilded and beautifully ennobled, by transferring the carbon print on glass, and pasting a piece of gold paper on the back. The picture looked then as if taken on a gilded background.

While I am speaking about the carbon process I will remark that they have tried here several times to introduce to the public the beautiful window pictures in carbon. Schaarwachter and Richardt exhibited many of them, but without success; the public prefer decidedly the paper pictures. Hereby I should not conceal the circumstance that the large carbon prints transferred on glass are not always durable. I am not speaking of the fading of the added red colouring stuff which changes the tone of the picture, but of the cracking of the film. All large pictures Schaarwachter produced in this manner are spoiled by cracking of the film, and on some of my own pictures the same fault appeared after a few weeks. I suppose this fault can be prevented by coating the glass on which the picture is to be transferred with gelatine; for the Woodburytype, which are brought in the market in large quantities, show no cracking.

For enlargement, the carbon process is coming more and more into use. The best method is that which I described some time ago. We have to prepare in the camera, by means of collodion, an enlarged diapositive from the small negative. Then we have to copy a carbon negative, which is to be transferred on glass; and from this we then print the positive picture. To the American photographer this method may seem perhaps too complicated; because for him, with so much bright sunlight, such a circuitous way is not necessary. But for us, with our gray northern sky, having even in summer very often dark days, the case is different, and the photographers of enlargements are in search yet of an artificial light fit for use.

In a previous letter I mentioned my testing experiments on the chemical strength of the electro-magnetic light. Recently I had occasion to test the light of a battery containing fifty of Bunsen's elements. The light appeared very glaring, but the strength was of inferior value. I had to expose my photometer eleven minutes before it showed fifteen degrees. I can produce the same effect cheaper with one and a-half grammes of magnesium wire.

There is at present much discussion about the worth of the carbon process, as I learn by your valuable periodical. I believe myself that the carbon process for small pictures can never displace the silver process, but gradually will come into use for large pictures. The great difficulty with which at first the process had to labour in warm weather is now removed in an easy manner. At the Royal Polytechnical Academy we are proceeding on warm days in the following way:—

1st. Prepare a bath:

Bichromate of potassium	4 parts
Water...	70 "
Alcohol	30 "

The same to be cooled by ice-water.

2nd. The carbon tissue is dipped in, back up, turned over quickly, so that the liquid moved so that the surface of the sheet will be moistened entirely, and then taken out immediately. During this operation the bath is coloured a little black by the paper, but while drying it does not run down even by 90° F. It is to be noticed that the tissue sensitizes quicker in high than in low temperatures, and therefore it needs only to remain in the bath for a short time. The paper is dry after two or three hours.

3rd. The copied papers are coated with plain collodion (one per cent. cotton), and dried in a dark place, then transferred by the squeegee, and developed. In this manner the work is just as safe as in winter time. By this process the reticulation and granulation of the film occur but seldom.

Speculative photographers have tried to join with the Russian or Turkish army, but till now have not succeeded, and, on account of mistrust, for fear they should make use of their art for treacherous purposes. In this war, it seems that photography will not perform an essential part, if Englishmen or Frenchmen are not more successful.

How many photographers are there in the world? What quantity of chemicals are they using? This question has recently occupied my mind very much. The answer is no easy one, and can be given only in part. In Germany the number of established photographers is a little over three thousand; in Austria and Hungary, about the same; and I hardly believe that this number will be exceeded in France or England. For Italy, Spain, Turkey, Sweden, Norway, and Russia, we can count only half the number, which gives the round number of twenty thousand established photographers in Europe. This number may be a low one in comparison with America, where, among forty millions of inhabitants, can be counted six thousand photographers. And in comparison with this number the consumption of albumen paper seems to be inferior. Germany manufactures the main part of it, which amounts to twenty thousand reams yearly. About one-third part is manufactured in other countries, so that to every photographer there is about one ream of paper. But the consumption of silver cannot be figured out so readily. In Germany the average use of nitrate of silver is three pounds yearly for each photographer, but in Austria, only one pound yearly. The reason is that there are existing in Germany large reproduction establishments, which Austria cannot show, and which are consuming a large quantity of silver. About the consumption of silver in other countries I could get no sufficient data.

The quantity of Bristol board consumed is an enormous one. In Germany forty millions of Bristol boards, cut in cartes-de-visite, are used annually. In fact, the photographer is giving out more money for Bristol board than for silver. Philadelphia Photographer.

CLEANING THE DAGUERRETYPE.

BY W. L. SHUMAKER.*

It certainly is a matter of vain regret that one feels, on removing a Daguerreotype from its case, that a specimen that represents such a wonderful era in the graphic art should be subjected to ruthless handling by many professionals of the present. We have had pictures of every kind brought to us for copying, and I find the Daguerreotype the worst abused of all.

Although I have never followed the art of Daguerreotypy, still I appreciate and admire the wonderful results that often pass through my hands.

A photographer sent us a package consisting of a large number of Daguerreotypes and ambrotypes. These were taken from their cases, their mats, glass, and preservers removed, each wrapped in a little piece of tissue-paper, the whole enclosed in a paper box; when received the ambrotypes were broken to splinters, and I had to practise the mosaic art to repair damages; the Daguerreotypes scratched to destruction.

About three years ago, two frames of Daguerreotypes, each containing about one hundred one-sixth size pictures, were sent to us to clean and replace. These pictures were placed in a velvet matt without sealing; the action of the gases of the atmosphere had obliterated most of the pictures, and they were unrecognizable.

To clean them and replace in the matt would have been easier than any other method, but I desired to make them a permanent thing; if I could, and tried the following experiment: first removing, brushing off all loose particles, then immersing in a dish of hot water; this removed all gum from sticking paper on back, and softened the coating on surface quickly, so that on laying in a dish of weak cyanide, they cleaned nicely; after washing well, I poured over the surface raw albumen, gave a slight rinse under a small flow of water, then set up to dry spontaneously. After thorough drying each was placed in a dish of alcohol for a few minutes; this caused the albumen to be made insoluble, or, in other words, cooked it.

If the albumen is moist in the least degree when placed in the alcohol, the surface will dry opaque, and trouble will be given to remove; it but if the surface albumen is thoroughly dry it will remain transparent, and dry spontaneously.

This method I found left a good coating on the surface, and could be rubbed quite hard without marking.

I hesitated making this public at that time, as I desired to wait and see if they returned to their original condition; but on examining them a few weeks since I found them all good yet, no change having taken place. I felt doubtful myself at the time, for all who have cleaned Daguerreotypes, although they may have sealed them properly when putting them up, will know that a picture once cleaned is more liable to change than ever, if not very carefully washed.

RESTORATION OF PRINT BATHS.

BY A. STOCK.†

UNTIL now it has been customary to treat silver baths, whether they have been employed for the dipping of plates or sensitizing of paper, in precisely the same way when defective or out of order, notwithstanding the fact that the print bath becomes contaminated with quite a different series of organic compounds and impurities. This should not be, for the latter requires, as a matter of course, special treatment, although, strange to say, no manual gives any definite information on the subject. The ordinary impurities that enter the print bath are gelatine or size, superfluous acid, and combination of the latter with the chloride salts employed in the preparation of the paper. The precipitation of

the gelatine matter, as of the organic compounds, is brought about by the following means:

1. The silver bath is treated with alum solution 1:10 strength (ordinary alum dissolved in hot distilled water), until small crystals are seen to form, when the liquid is filtered. These crystals are silver albuminate, which are dissolved again in hot distilled water, and added to the silver bath again; a portion remains dissolved, while the rest again separates. This silver albuminate may be employed, therefore, again and again.

2. By adding and filtering off again burnt alum or hydrated clay, for, as is well known, the oxyhydrate of aluminium possesses a considerable tendency to combine with organic substances, and precipitate the same when in solution. As the hydrated clay exerts the same action against colour, it is far preferable to permanganate of potash when any discolouring of the bath takes place.

If the print bath is acidified pretty strongly with acetic acid, and the kaolin added until the smell of acetic acid has disappeared, and the whole filtered, then the sizing material is also completely coagulated by the acetate of aluminium which has been produced.

There remain still the different acids and their salts to neutralize and decompose. To do this, carbonate or bicarbonate of soda has hitherto been recommended to be employed. Now, although both those compounds, and especially the latter, are excellent agents for neutralizing the silver bath, I have never found the result to be a marked improvement in the bath.

On the other hand, we possess in caustic potash and soda two excellent means in neutralizing and decomposing acids and salts present in the print bath. Both are dissolved in ten parts of distilled water. From one of the two solutions (the first is to be purchased of any chemist) enough is added to bring about a gelatinous precipitate, the liquid being from time to time vigorously shaken. The silver bath now assumes a transparent, milky turbidity, or, if it does not, more caustic potash is added, until the turbidity does not disappear, and litmus paper betrays a neutral reaction. This gelatinous precipitate cannot be filtered off, either by means of bibulous paper or cotton-wool, as all the pores are very soon plugged, and only moistened linen or flannel can be used for the purpose. The linen or flannel is strained tightly upon a square wood frame, and the liquid poured in the middle; the strainer must not touch at the bottom, but remain free. Neither must it be pressed, as in that case some of the gelatinous precipitate is forced through. It is well to let the filter process go on during the night, and then there is plenty of time for the liquid to run through bright and clear. Those who are not conversant with this method of filtering or straining should be initiated into it by a chemist. After the operation the cloth may be dried, and be employed again. In adding various substances to the print bath in order to purify it, one need not be nervous about going to work, for there is no harm in being a little out, and the print bath does not require such delicate handling as is the case with the negative bath.

Print baths treated in the manner described will be found to possess all the properties necessary to good working, and to impart to albumenized papers the finest lights and shadows. At the same time, the restoration of a print bath should not be delayed for any length of time, as sometimes happens with the negative bath, but should be treated periodically, especially so far as neutralization with caustic potash is concerned. If the bath becomes too alkaline, it may easily be rendered neutral again, after straining, by the careful addition, drop by drop, of pure citric acid.

In the above lines I have desired to indicate the theory involved in the proper restoration of the print bath, and thus to acquaint my friends with the why and wherefore of the reactions.

Dr. Liesegang, in connection with the subject, points out the method employed by Mr. Maxwell Lyte to purify a turbid, brown print bath, a method which Dr. Liesegang

* Philadelphia Photographer.
† Photographisches Archiv.

has somewhat simplified. The following solution is prepared:—

Spring water	100 grammes
Phosphate of soda (crystallized) 5 ..	
Carbonate of soda (crystallized) 20 ..	

To every litre of brown print bath are added ten grammes of the above solution, the whole being vigorously shaken and then filtered. The bath runs through the filter perfectly bright and clear. Afterwards for every ten grammes of the above solution that have been employed, there is added to the print bath one gramme of nitrate of silver. The residues collected upon the filter-paper should not be thrown away, but added to other silver residues to be worked up at a fitting opportunity.

EMULSION MANIPULATIONS.

BY H. J. NEWTON.*

ALTHOUGH so much has been said and written on the mode of developing and the general manipulation in the production of an emulsion negative, there still appears to be a call for light, and from some quarters this cry is fierce and sharp. The fact appears to be overlooked by some that by making a conspicuous display of their failures they put themselves in strong and unfavourable contrast with those who succeed, and to a great extent justify adverse criticism as to their intellectual capacity.

To avoid the necessity of answering some correspondent almost every day, I will give in minute detail my mode of manipulation in producing an emulsion negative.

First, prepare the plate either with albumen or talc. If with albumen, prepare it as follows: White of one egg dissolved in eight ounces of water; after the solution is complete, add eight ounces of water to which have been added sixteen drops of carbolic acid. Ammonia in the albumen should be avoided. If talc is used, clean the plates with undiluted sulphuric acid; wash well, and wipe dry with a clean cloth which has been washed in water containing washing soda instead of soap, and when dry apply the talc. If the plate is to be exposed and developed while wet, place it in clean water as soon as the film is set, and let it remain until the greasy lines are washed off (after this is accomplished, it will not injure it if it remain in the water for a week); expose, and before developing flood the surface with water, in order that the developer may go smoothly over the surface. A quantity of the soda solution, sufficient to cover the plate, is poured into a wide-mouthed vial, and, just before using, a few grains of pyrogallie acid are put into it, which dissolves in a few seconds by agitating the soda: then flow over the plate. The flowing of the plate with the developer can be done moderately, as nothing is gained by dashing it on as many do the iron developer in developing a bath negative. If the plate has been over-exposed, the appearance of the negative on the application of the developer will be the same as that of a bath plate.

I would advise any one commencing the use of emulsion to expose one or more plates in this way: Prepare a plate, and give it three exposures by drawing the slide so as to expose one-third of the plate, and after ten seconds draw it so as to expose two-thirds of the plate, and give this ten seconds, and then draw the slide so as to expose the whole plate, and give this ten seconds. In this way the first part of the plate gets thirty seconds, the middle part twenty seconds, and the last ten seconds. By developing a plate so exposed, you can approximate very near the proper time for the light you are working in.

The great variation in the actinic force of light in different localities is a fact, to a great extent, overlooked by photographers. The light from the rear windows of my residence in the yards between the residences on Forty-second and Forty-third Streets is at least twice as strong in actinic force as that in the Central Park, three quarters

of a mile away. Before going to the Park to expose plates, I always expose a small plate from my window at the rear of my house, and if fifteen seconds makes a good negative, I invariably give from thirty to forty seconds in the Park. The most striking illustration, however, of the difference in different localities of the actinic force of light I observed in making negatives at Niagara Falls. Plates which required thirty seconds' exposure in New York were fully exposed at the Falls in from three to six seconds.

From these facts it will be observed that when one attempts to state definitely how much exposure should be given for a specific quality of emulsion, the chances are that he only would mislead; for this reason it becomes necessary to expose a plate as above directed, and thus determine the action of light in which the emulsion is exposed.

If the plates are to be used dry, the process of development is the same. The plate should be thoroughly washed before applying the developer. I usually, however, flow the plate after washing with a pyrogallie acid solution, from three to six grains strong, until the faint outlines of the image appear. This pyro solution can be used repeatedly for several hours.

I determine in this way whether the exposure has been long or short. If the image comes out quickly and has a reddish appearance, it indicates an over-exposure. I then reduce my soda solution by adding a small quantity of water—in the first place one-fourth—and determine by its action how to treat the next plate.

Some failures to get good negatives from emulsion have been caused by washing the plates in water unfit for the purpose. Organic are less objectionable than mineral substances in the water. Water from melted ice is always good for this purpose.

The greater the quantity of pyrogallie acid used, the more intense will be the negative. There is, of course, a limit to this effect of pyro. If the negative after fixing needs strengthening, use the iron and citric acid as follows:

No. 1.—Water	16 ounces
Protosulph. iron	1 ounce
Citric acid	$\frac{1}{2}$ "
No. 2.—Water	1 ounce
Silver	20 grains
Nitric acid... ..	6 drops

Pyro and citric acid can be used, but are more likely to produce stains, and in my hands are not so satisfactory as the iron.

AN IMPROVEMENT IN THE FIELD CAMERA STAND.

Anthony's Photographic Bulletin says:—

"This is a suggestion of Captain A. J. Russell, who has had a large experience in practical out-door photography. Conceiving the idea to be of considerable importance, we have secured letters-patent on it, and take pleasure in presenting it for the approval of the trade.

"The accompanying diagrams of the top, open and closed, will very readily convey an impression of this serviceable little improvement, which enables the out-door photographer to quickly dispose of what has hitherto been one of the most troublesome parts of an outfit to be carried.

"The peculiar form of the old tripod too required, in

* *The Photographic Times*.

packing, a certain amount of space quite disproportioned to its weight. Russell's tripod top, it will be seen, folds into a perfectly straight piece, which can easily be carried in the pocket. Being made of hard wood, and tipped with brass plates, it is thoroughly firm and substantial. The legs do not fold. The price is \$7 50, complete."

THE CYANOTYPE PROCESS.

It is not unusual, as every photographer knows, for a process to remain *perdu* for some years, and then to get made known again with some mystery and circumstance. We see old friends revived in this way from time to time, and, like somebody whom we meet for the first time in a quaintly shaped hat or a different-coloured coat than usual, we fail to recognize him at the first moment of our rencontre. But it is only for an instant that the deception holds good, and the well known features are as apparent as ever as soon as we get on close terms again. The cyanotype process, as Sir John Herschel used to call it, is the latest attempt at "fraudulent enlistment," and the circumstance that we have here to do with a genuine article, and not a spurious one, does not make the deception the less barefaced. The cyanotype process as practised by Sir John Herschel is a very simple affair, and one that is found extremely useful for copying outline sketches or multiplying tracings, instead of using tracing-paper. Sir John Herschel employed it, as does Professor Herschel, of Newcastle, to the present day, for making copies of their calculations of astronomical tables, the characters or figures being produced in white upon a blue ground. The paper, ready prepared for use by draughtsmen or others, is to be purchased in Paris; and also, we believe, in this country, of Messrs. Marion, of Soho Square; but those who desire to make it for themselves can easily do so. Good, smooth paper is treated with

Citrate of iron (or ammonio-citrate)...	140 grains
Red prussiate of potash	120 "

Dissolved together in two fluid ounces of water. The solution can be kept in a glass-stoppered bottle well wrapped up in a dark cloth, or shut up in a dark cupboard, for any length of time. It is applied by means of a brush or tuft of cotton-wool, and the surface dried in the dark. The paper is exposed to light under a tracing, being kept flat by glass plates, and the print fixed by washing in clean water for a few minutes. The ink lines of the tracing must be of an opaque black, such as India ink, &c., to prevent the rays of light from passing, and, as a matter of course, the copy will not be sharp unless the paper is kept firmly in contact with the tracing.—*Times*.

THE CAUSE OF RETICULATION IN CARBON PRINTING.

BY ADOLF OTT.*

AMONG the chief difficulties attendant on carbon printing may be ranked reticulation, a phenomenon which appears sometimes in tissue that is otherwise faultless. This defect has already given rise to much discussion; indeed, one may say that it has become the question of the day among carbon printers and in the photographic journals, and all sorts of means have been suggested with a view to remedying the evil.

The cause of reticulation is attributed by some to a too rapid drying of the tissue, and by others to the operation being conducted too slowly; others, again, put down its cause to the use of a weak bath, or to the addition of acid in the warm development bath, &c. Nobody, however, seems to have thought that the reason was connected in some way with the condition of the atmosphere around.

We do not wish to assert that reticulation is alone and only due to the state of the atmosphere, for this would not at all coincide with the conditions under which it has

been from time to time observed. For instance, it has been found that prints in the establishment of M. Braun, produced by the double transfer process, exhibited the evil, while other pictures secured at the same time, and with the same tissue, but by the single transfer process, were altogether free from the defect. A careful examination with a magnifier quite failed to show any tendency of reticulation in this latter instance, although it was distinctly seen in the other. This circumstance is in harmony with the fact observed by Woodbury, that the addition of certain pigments to chrome gelatine gives rise to a grain-like network, which some gelatines show more readily than others. In all these changes the gelatine seems to lose a good deal of its adhesive properties. In dilute alkaline solutions pigment pictures also quickly become reticulated, and then dissolve readily from the paper.

Without particular care is taken, reticulation also occurs, one might almost say invariably, when the air is charged with electricity, as, for instance, just before a thunderstorm. Manufacturers of gelatine are, indeed, well aware that during a storm of this kind the material is readily decomposed, while of my own knowledge I can say that the same kind of decomposition is to be brought about by passing a galvanic current through a gelatine solution; this M. Ferdinand Brown has amply proved by experiment. It seems as if there are in this, as in other organic substances (I am speaking now of non-sensitized tissue), microscopic organisms which are set into more energetic activity by the electric medium. The circumstance is known to all that milk soon becomes sour in a thunder storm, and exhibits organisms under a microscope. A Frenchman has, indeed, suggested that the action of yeast, or fermentation, might be facilitated with the aid of electricity.

Under the supposition that the drying is undertaken in as cool as possible an apartment, the addition of spirit to the chromate bath to the extent of about twenty-five to thirty per cent. is to be recommended. Firstly, because in this way the drying of the gelatine is thereby hastened; and, secondly, because the alcohol acts, very probably, like carbolic or salicylic acids, as a preservative. The finely-powdered bichromate is first of all dissolved in water in the proportion of—

Bichromate of potash ...	4 to 5 parts
Water	70 to 75 "

and when the bichromate has been all dissolved, the spirit is added. As a rule, a very fine precipitate is formed, which must be filtered off. And, by the way, I may remark, that it was not Vidal, but an American gentleman, Land, who first suggested this addition of alcohol.* Land thought to avoid the running of the gelatine film in this way, and he recommended an addition to the bichromate bath of twenty-five to forty-five per cent. of its volume of alcohol, when working at a warm temperature, such as 90° to 100° Fahr. At M. Braun's establishment at Dornach the addition of alcohol to the bichromate bath has been customary for a long time.

Friedlin, of Munich, recommends, as a preventive, carbolic acid, and gives the following formula for the bichromate bath:—

Bichromate of potash ...	120 grammes
Distilled water	3200 "
Carbolic acid (fluid) ...	4 "

I have not sufficiently experimented to pronounce upon this formula, but I cannot help thinking that a small addition of carbolic acid would be beneficial.

The decomposition of bichromated gelatine by the atmosphere seems based on purely chemical reaction, for it can hardly be supposed that such delicate organisms as those which are formed in decomposing gelatine could withstand the action of bichromate salts. A few experiments would, however, soon settle the question; my task was simply to put photographers on their guard during the present hot and stormy weather.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE forty-seventh annual meeting of the British Association has just closed, in the fine city of Plymouth, where thirty-six years before the peripatetic philosophers held festival. As we have more than once remarked, in reference to recent annual meetings of the Association, photography as a special science has been gradually ceasing to receive attention. When the Association was young, photography was still younger, its discovery having been announced when the Association had only been a very few years in existence. As was quite natural, the little stranger was heartily welcomed, and its new developments, capacities, and requirements, were studied year by year. Chemists and physicists were eager in their investigations and experiments in various branches of the new art-science, and at every meeting of the Association many papers directly connected with photography were read by distinguished savans.

The days when Wheatstone and Brewster and men of similar stamp took a working interest in the art and its possibilities have passed, and photography has ceased to be regarded so much as a science in itself, as an established recognized and understood aid to investigation in other sciences. And in this aspect photography still appears prominently at the meetings of the Association. Captain Abney, Mr. Mallock, and Lord Rayleigh, read interesting papers more or less connected with photography, and many other gentlemen described the application of photography as contributing to their investigations. In the department of Anthropology, Mr. Francis Galton referred to some interesting uses of photography. In searching amongst the habitually vicious classes for some general and similar outward indications to mark mental characteristics, he remarks that by some trustworthy method of observation and record of this kind "we should learn how far the more obvious physical characteristics may be correlated with certain mental ones, and we should, perhaps, obtain a more precise scale of temperaments than we have at present. Having obtained drawings or photos. of several persons alike in most respects, but different in minor details, what sure method is there of extracting the typical characteristics from them? I may mention a plan which had occurred both to Mr. Herbert Spencer and myself, the principle of which is to superimpose optically the various drawings, and to accept the aggregate result. Mr. Spencer suggested to me in conversation that the drawings reduced to the same scale might be traced on separate pieces of transparent paper, and secured one upon the other, and then held between

the eye and the light. I have attempted this with some success. My own idea was to throw faint images of the several portraits in succession upon the same sensitized photographic plate. I may add that it is perfectly easy to superimpose optically two portraits by means of a stereoscope, and that a person who is used to handle instruments will find a common double eye-glass fitted with stereoscopic lenses to be almost as effectual and far handier than the boxes sold in shops. It is needless to enlarge on the obvious fact that many persons have become convicts who, if they had been afforded the average chances of doing well, would have lived up to a fair standard of virtue. Neither need I enlarge on the other equally obvious fact, that a very large number of men escape criminal punishment who in reality deserve it quite as much as an average convict. Making every allowance for these two elements of uncertainty, no reasonable man can entertain a doubt that the convict class includes a large proportion of consummate scoundrels, and that we are entitled to expect to find in any large body of convicts a prevalence of the truly criminal characteristics, whatever these may be."

Again he remarks, on this subject:—

"The ideal criminal is deficient in qualities that oppose his vicious instincts. He has neither the natural regard for others which lies at the base of conscience, nor has he sufficient self-control to enable him to consider his own selfish interests in the long run. He cannot be preserved from criminal misadventure, either by altruistic or by intelligently egotistic sentiments. It becomes an interesting question to know how far these peculiarities may be correlated with physical characteristics and features. Through the cordial and ready assistance of Sir Edmund Du Cane, the Surveyor-General of Prisons, who has himself contributed a valuable memoir to the Social Science Congress on the subject, I was enabled to examine the many thousand photographs of criminals that are preserved for purposes of identification at the Home Office, to visit prisons, and confer with the authorities, and, lastly, to procure for my own private statistical inquiries a large number of copies of photographs of heinous criminals. I may as well say that I begged that the photographs should be furnished me without any names attached to them, but simply classified in three groups according to the nature of the crime. The first group included murderer, manslaughter, and burglary; the second group included felony and forgery; and the third group referred to sexual crimes. The photographs were of criminals who had been sentenced to long terms of penal servitude. By familiarising myself with the collection, and continually sorting the photographs in tentative ways, certain natural classes began to appear, some of which are exceedingly well marked. It was also very evident that the three groups of criminals contributed in very different proportions to the different physiognomic classes. I have thus far spoken of the character and physiognomy of well-marked varieties of men. The anthropologist has next to consider the life history of these varieties, and especially their tendency to perpetuate themselves, whether to displace other varieties and to spread, or else to die out. In illustration of this, I will proceed with what appears to be the history of the criminal class. Its hereditary perpetuation is a question that deserves more careful investigation than it has received, but it is on many more accounts more difficult to grapple with than it may at first sight appear to be."

We have selected these examples of the uses of photography in a somewhat novel field as likely to interest many readers, and as suggesting the importance in photographs for purposes of this kind of presenting unsophisticated pictures. Naked photography is not always absolutely true, but the nature and amount of error may be estimated and allowed for; whilst the modifications produced by retouching are beyond estimate.

Some further details of the Association's doings will be found on another page.

PHOTOGRAPHY IN AMERICA.

BY NORMAN MAY.*

OWING to the much clearer atmosphere and greater amount of actinism in the light, exposures are much shorter in America than in England's "muggy" climate. I have seen printed over fifty prints from one whole-plate negative in a day; of course the negative was rather thin (don't think the story is too), and it was printed in the sun, but they were all off by three o'clock. In consequence of the brighter light, American photographers, as a rule, are very successful indeed with children, catching, almost instantaneously, their often charming and always fleeting expression. I remember seeing at a Canadian exhibition a frame filled entirely with children's photographs, the majority of them babies, the various expressions, from grave to gay, being exquisitely rendered. Fogs are rare, and the drizzling rain so common in England is there almost unknown. When it rains, it generally rains heavily, and it's no uncommon thing to have hail-stones as large as marbles, which, pattering on the shingled roofs, make a great noise. Lightning is of nightly occurrence in the hot summer of the Western States, generally sheet or heat lightning, forked lightning only occurring in a storm, but then extremely vivid. Altogether, it is a country of much greater extremes than England in every way. The mountains are higher, rivers are larger, the cold is greater, and heat more intense, big cities spring up with big hotels, long railways go across immense plains, go through almost interminable forests, down into deep valleys, and over high, snow-clad hills.

It is a country of inexhaustible resources, great enterprise, and wonderful vitality, with circumstances in favour of its future that no European power possesses. Everything has lately been done at too high pressure speed, but even now that is being amended, and when this period of commercial depression is past, everything will find its level, and they will prosper again, if more slowly, yet more steadily and surely.

The emigrant, should he fail to do as well as he expected, will find the experience he has gained, the new ideas he gets, and the enlargement of his general knowledge, amply repay him for his expenditure and loss of time.

In drawing these remarks and imperfect jottings to a close, I will endeavour to disabuse the mind of the intending emigrant of the idea that the American photographers are in any way inferior to the English, and that his abilities will be recognized as pre-eminent. English people are not liked so well by the Americans as the Germans, who make far the best settlers; and the emigrant will find he must give up entirely his old notions, begin afresh, and adapt himself to the people. If he cannot do that, he has not a shadow of a chance of success.

BRITISH ASSOCIATION.

THE real work of the Association commenced on Thursday morning week with the addresses of the Presidents of the several sections, and the attention with which the introductory address by Professor Allan Thomson, on the previous evening, had been listened to, showed that the members were fully equal to the labours which they prospectively had to bear. In our columns it would be unwise to discuss the character of the President's address; suffice it to say, that amongst those who understood the biological questions involved, it was deemed a masterpiece, and to show the growth of Darwinism in the last ten years. It is only in Section A (Mathematical and Physical Science) and in Section B (Chemical) that matters photographic are discussed, unless it be in the Geographical Section, where the aid of the art-science to travellers is discussed. In the present year, the only

points which have been raised having a photographic bearing have been in Section A. In the address of Professor Carey Foster, with which the proceedings were opened, we have a really practical proposition, and one which, in the interest of science, it is to be hoped may be carried out. He proposes that committees formed of eminent men of science shall be appointed to draw up reports of the progress of the different branches of physical science as a record, and present them to the British Association. He does not propose that the reports shall be annual, but that each year a report on some one branch of science shall be presented for insertion in the proceedings. Thus in one year there should be a report on the progress of optics, in another of astronomy, and so on. By the adoption of this plan it is evident that if the reports be carefully drawn by men eminent in those branches of science on which the report is to be drawn, and who represent all complexions of opinion, a most valuable addition to the work of the Association will be produced, and one which will lend a much greater value to the annual reports than at present attaches to them. Should such a plan be adopted, which we have every reason to hope will be the case, we may feel confident that photography will not be neglected, since in nearly all physical research it has proved, and still more might prove, a valuable handmaiden to the scientific worker.

There are indisputable proofs that photography at present has not been utilized to its fullest extent in these researches; and the cause is not far to seek. The man who is occupied in physical research is rarely a practical photographer; and in many cases of which we are aware, the difficulties to be surmounted in learning the art have debarred its employment when it would otherwise have been utilized. It may perhaps be too much to say that one of the elements of all scientific education should be to include a thorough knowledge of photography; but at all events, the progress in science shows that a practical acquaintance with its rudiments is daily becoming more and more a necessity. The reports suggested by Professor Foster will in all probability help to give the needful stimulus in this direction, since they cannot do otherwise than show the labour that may be saved by using a sensitive plate as a recording agent, instead of the eye.

The opening address of Professor Abel, F.R.S., was also well worthy of the attention with which it was heard. His reproof to those young workers in organic chemistry whose sole proof of a new compound might, perhaps, consist solely of the determination of a boiling point, was particularly happy. He also ably supported the claims of analytical chemists against the synthetical workers, and his dictum that the discoverer of a good analytical process was certainly on an equality with the discoverer of a new organic compound was greeted with an applause which showed that the true spirit of chemical science was fully appreciated by the majority present. Whether it be that photography has sunk to a more commercial status than in its earlier days, or that those who practise it are not of the same stamp as in those days when the names of Herschel, Hunt, Claudet, and such were heard at the British Association in connection with it, may be a disputed point. One thing is, however, quite clear: the prominent position which it should occupy at the British Association is not maintained, though we have no hesitation in saying that it might be restored.

The subjects of principal interest during the meeting have been the Telephone and the Colorado Beetle. Dr. Bell, the inventor of the Telephone, met with a most hearty reception, and the experiments he carried on with Mr. W. H. Preece will long live in the memory of the Association.

There have been the usual soirées on two evenings, an art exhibition having been included in their attractions. This exhibition was replete with high-class paintings, both in oil and water colours, lent by various nobility

* Continued from page 398.

and gentry of the county and neighbourhood, and was well worthy of a careful inspection. It was free to all members of the Association, many of whom have taken advantage of the privilege.

Subjoined will be found reports of papers by Captain Abney, F.R.S., Professor Vernon Harcourt, and Lord Rayleigh, F.R.S. A communication by Mr. A. Mallock, on "Measurement of Height of Clouds," we are obliged to hold over till next week.

ON A METHOD OF SHOWING THE SUN'S ROTATION BY SPECTRUM PHOTOGRAPHY.

BY CAPTAIN ABNEY, F.R.S.*

THOUGH it is now generally admitted that the approach or retrocession of the stars towards our system can be observed by means of the displacement of the absorption lines of their spectra towards the most or least-refracted end of the spectrum, yet, in the minds of some, there still exists a lingering doubt of the truth of the process employed. If, however, the displacement of the absorption lines due to the rotation of the sun can be shown to agree with the theory, all doubt must be removed. Huggins, Christie, and Young have proved the solar rotation to their own satisfaction; but with the methods employed there might be some danger that the displacement noted was due to some other cause. I have made some experiments lately in the same direction, which have, I think, been fairly successful in conclusively demonstrating the truth of the problem, the manner of which I will briefly describe:—

A condenser was prepared by cutting a lens across the centre and mounting the two halves side by side, in such a manner that the two images formed by the sun were tangential one to another, the tangent being parallel to the horizon. The light from the sun was thrown into this condensing arrangement by means of a heliostat having a mirror silvered on the surface; and the images were brought to a focus on the slit of a spectroscope, the point of contact of the two suns occupying a position half-way down the slit. To the spectroscopic apparatus was attached a camera and lens of some six or seven feet focal length, and the spectrum was thus formed on a sensitive plate. When the north and south points of the sun's image were tangential, evidently no displacement of the two portions of the spectrum formed by the upper and lower halves of the slit should be seen; whereas, when the equatorial portions of the images were in contact, the displacement of the lines should be that due to double the rotation, since the eastern limb should be receding and the western advancing.

Thus, if photographs were taken in the morning, at noon, and in the evening, the apparatus remaining in the same position, it is evident that a displacement of the lines in the top half of the spectrum should first be noted in one direction; next, there should be no displacement of the lines; and, finally, there should be a displacement of the lines in the top spectrum in the reverse direction to that first noted. On the two separate occasions on which I have devoted a day to this subject I have found such to be the case. In the first I was using a refraction apparatus of considerable power; in the second I employed a diffraction grating by Rutherford, of over 17,000 lines to the inch, which Mr. Lockyer kindly placed at my disposal. The fourth order of the spectrum in the last case was employed, and that portion lying about the H lines was taken to test the method. I have not had sufficient time to measure the displacement of the lines, but as far as I have gone, the truth of the method first employed by Huggins, as applied to the stars, is fully borne out.

* Read before the British Association in Section A—Mathematical and Physical Science.

A NEW STANDARD UNIT OF LIGHT.

BY V. HARCOURT.*

PROFESSOR VERNON HARCOURT introduced a new standard light for photography to the meeting. He first described the difficulties encountered in measuring the light of gas, owing to the variation in the light of the standard sperm candles due to one cause or another. Thus the height of the barometer and thermometer had always to be taken into account in order to correct the results. The Carcel lamp unit he also alluded to, and pointed out that the uncertainty of the composition of the oil, the height of the wick, and other points, were disturbing causes in the intensity and quantity of the light. In order to get a standard light, he had fixed certain requisites: first, that the combustibles should be of a known composition; and, second, that the same amount should be burnt in a given time, also that the atmospheric changes should have a minimum effect. These conditions he effected by distilling petroleum at 50° Cent., and collecting the distillate. One volume of this petroleum in a vaporised state with three of common air gave the necessary combustible, which could be held in a gasometer. A unit of his light consumed half a cubic foot an hour when burnt at an orifice of a quarter of an inch in diameter. The colour of the flame seemed very similar to that of the ordinary gas flame, and hence was suitable for the purpose required of measuring the illuminating power of the latter. By using a gas to give a standard light, no correction for temperature or pressure is required, since it and the gas under examination are similarly affected. Perhaps such a standard light might be useful to photographers by which to determine sensitiveness of various photographic compounds. The expectation of the Section was raised to hope that perhaps some definition of what really constituted white light might be given; but they were doomed to disappointment.

THE LOWER LIMIT OF THE THERMAL SPECTRUM.

BY LORD RAYLEIGH, F.R.S.*

LORD RAYLEIGH read a paper on "The Lower Limit of the Prismatic Spectrum," in which he alluded to the researches of Sir J. Herschel on the thermal spectrum. (See Hunt's "Researches on Light" for a figure). He gave a resumé of the two methods Sir J. Herschel adopted of tracing the limits of the spectrum. In the first, he coated one side of a paper with lamp-black, and then brushed alcohol over the other and exposed. The portions where the dryings first took place indicated the thermal maxima. These points he had called α , β , γ , and δ , and stated he also found traces of another maximum ϵ . Lord Rayleigh had repeated these experiments, but with different results to those above mentioned. He found that he got no results beyond β . What led him to undertake the investigation was the theoretical probability that the change in the refractive index in a prism for different rays must have a limit, and if such were the case the thermal spectrum should stop abruptly. He explained how this theoretical limit was arrived at. If the prism receiving the sun's rays were set at the angle of minimum deviation for each ray, and the length of the spectrum were taken as the abscissæ, and the ordinates formed of the refractive indices, it would be found that on joining these ordinates a nearly straight line was formed, which would cut at a certain distance from the limit of the visible spectrum, between which points the invisible thermal spectrum must lie. The limit of Sir John Herschel's thermal spectrum lay far beyond this point, and it was to rectify these results that Lord Rayleigh undertook the investigation. By the alcohol method he found his own to agree with theory. In order to further test his results, he repeated Sir John's experiments, which he made by brushing over paper—whilst

exposed to the spectrum—ferricyanide of potassium and oxalate of iron. This combination readily changed in the thermal rays to a brownish colour, eventually changing to Prussian blue. In these experiments he found the same results obtained. He had brought before this Section these experiments in order to obtain an elucidation of the seeming discrepancies. He said that if the base of the prism used by Sir John were polished, the internal reflections from the surfaces, perhaps, might be the cause of it. (This was the case in the prism that Sir John used). In answer to questions put to him, Lord Rayleigh stated that, although in his experiments he had employed a carbon disulphide prism, yet he had obtained the same results when using flint glass or rocksalt prisms.

Mr. Spottiswoode said that in some polarized heat experiments he had found an abrupt termination of the thermal spectrum.

Captain Abney, on being called upon by the President, said he had not much to add in the matter. In photographing the ultra red end of the spectrum, he had found that the state of moisture in the atmosphere had affected light obtainable in a marked degree, and suggested that this, perhaps, might be the cause of the discrepancy.

Lord Rayleigh said that he had placed a cell containing water before the prism, and had found it diminished the length of the thermal spectrum considerably; but he did not think this accounted for it altogether. Four inches of water, he said, represented the moisture in the air when entirely saturated, and the thickness of water he used was a fair representation of the amount that might be expected to intervene between the sun and the prism. He hoped other experimenters would repeat his experiments.

ASSER'S PHOTO-LITHOGRAPHIC PROCESS.*

THE Asser process differs from those generally in use principally in regard to the paper employed, which is not sized or gelatinized, and, consequently, though bad for transferring, nevertheless is capable of fulfilling a special rôle. Asser employs an unsized paper, which he simply coats with a little starch paste, dries, and floats upon a bichromate bath. It is possible by means of his process to secure prints in greasy ink from portrait-negatives, which exhibited in the half-tones an agreeable grain, and were very similar to Lichtdrucks which have been pulled from grained glass plates. The half-tone is very well reproduced, and it is evident that in certain directions the process will find many applications.

As the process, though an old one, has not recently been referred to, an account of the *modus operandi* may be welcome. You take unsized paper of medium thickness, and of as fine a texture as possible, and apply to the surface of the same, by the aid of a clean sponge, a thin film of starch dissolved in water. After the paper, hung up on a pin, has dried, it is floated, the coated side uppermost, upon a saturated solution of bichromate of potash in distilled water, with which it is at once impregnated; consequently the paper is permitted to float upon the solution but a very short time. It is then hung in the dark to dry, and at the lowest corner is put a tiny piece of bibulous paper to absorb the superfluous liquid.

As soon as the paper has completely dried, it is put into a printing-frame, the starch-coated side against the negative, which should be pretty vigorous and clear. After printing for a longer or shorter time, a clear, brown image appears upon an orange-yellow ground. When sufficiently printed, the paper is put, image uppermost, in a water bath, care being taken that no air-bubbles are formed between paper and water.

It is allowed to float on the water (in the dark) until all the bichromate of potash which has not been acted upon by light is dissolved out, and the picture appears clear

and of a light brown colour; it is then taken out of the water and dried, first of all between leaves of blotting-paper, and then in the air. After drying, the picture is put upon a marble slab, made very hot, taking care, however, that the print does not become brown by heating. By undergoing this operation of heating, the chromate salt is endowed with the property of readily attracting the printing ink.

A piece of unsized paper, rather smaller than the picture, is now moistened, flattened upon a piece of patent plate, and the superfluous water removed by the aid of filter paper. Then the image is floated upon its back for a few seconds upon warm water until the water has moistened through the paper and wetted the coating of starch. The image is then taken out of the water and placed upon the sheet of moist paper lying upon the patent plate; in this position the two surfaces are placed in contact, and covered with a dry sheet of sized paper, the latter being rubbed over in all directions by means of a soft cloth, so that the moisture penetrates uniformly, and the whole becomes firmly adherent to the glass plate. The sheet is then taken away, and the image laid bare.

In the meantime a stone is brought such as lithographers employ, together with printer's ink and litho. ink, which is mixed by means of a little oil varnish. With this ink, applied to a bit of flannel, a roller covered with fine cloth is coated as uniformly as possible; the roller is then carefully and without pressure rolled over the image, which soon becomes black, and rapidly assumes vigour as the rolling goes on, while the whites still remain perfectly white. The picture is then in a position to be transferred to stone; the application of the ink to the image must not be carried too far.

While the paper is yet damp (so that the paste may adhere to the stone), it is laid upon a lithographic stone and passed in this way through the press. If the paper holds too fast to the stone, so that it cannot be detached, a little damping of the paper soon brings this about. The image is then to be seen clear and sharp upon the stone, and the printing off of copies can then be proceeded with in the ordinary manner in any lithographic work-room.

The paper employed in the process for the transfer, being unsized, is easily penetrable by water. Portions, however, of the paper, where the light has acted upon the bichromate of potash covering it, do not become moistened. These parts of the paper, indeed, when heated, will permit any ink to adhere at once.

Unsized paper upon which is formed a print in bichromate of potash, after being heated and moistened with water, behaves, in a word, exactly in the same manner as a lithographic stone; some portions of it attract the ink, while others repel it. Where the light has acted, there the surface becomes hard, and the ink adheres; whereas the other portions absorb water, and in this condition repel the ink.

If the paper is covered on the image surface with starch, the transfer will have more solidity.

COLLOTYPE PRINTING.

A CORRESPONDENT sends us the following:—

"One of your articles in last week's issue, while notifying the fact of the illustration of a magazine with a Woodbury portrait as a proof of a new advance in mechanical photographic printing, appeared to lament as a fact the absence of outward and visible signs of progress in the Collotype or fatty ink process. Collotype, it was said, had proven, by numerous perfect specimens, its potential ability in photographic printing; but as a real active factor in the multiplication of sun prints it was hinted to be 'no where' in the running, in consequence of the immense difficulties—chemical, lithographic, &c.—which beset the process.

"That the difficulties have been real enough there can be

no doubt; but that, to a very large extent, they have been surmounted has been incontestably proved to the writer. The fact is that, while Collotype is making a distinct and lasting impression in the field of literary illustration, its employment has been in channels that do not come under the notice of the ordinary reader, and is distinct from the usual work of the professional photographer.

"I recently had the pleasure of inspecting the Collotype department of the Autotype works, and, by the courtesy of the director, had not merely an opportunity of observing the details of the printing, but of carefully examining the quality and character of the work which was steadily issuing from seventeen out of the twenty vertical presses at present worked at Ealing Dene. I had the advantage of special introduction to the proprietors, contemplated an arrangement to introduce the process into an important colony, and received, probably, a special amount of attention.

"I may say that I was fairly astonished at the nature of the work being done; it was so much more special and second-rate than I had expected, and although evidently a sound commercial enterprise for an empire like the British, I felt it not likely to answer my purpose at the Antipodes. Three of the largest presses (the matrix plates being inked up and manipulated by women) were devoted to the production of copies of ancient charters for the trustees of the British Museum; and although impressions on demy were yielded at a comparatively slow rate (only ten or twelve per hour) yet the result of the deliberate care was a series of admirable, uniform, perfect prints that reproduced M.S.S., stains, time marks, and texture of the original, whether parchment or papyrus, in a wonderful manner. I have since seen some of these Autotype copies under glass at the British Museum for the benefit of the public, and ascertained that the institution issues editions of five hundred and upwards, strongly bound, at less than cost price, for the benefit of museums in general and the pundits in particular.

"Another press was engaged on somewhat similar work for the Palæographical Society, which issues quarterly to its three hundred and fifty subscribers a fasciculus of some twenty-four examples of the rarest and most interesting parchment writings in existence. I understand that the Palæographical Society is one of the most flourishing of our learned bodies, and that it owes its origination to the fact that photography, by the Collotype process, offered such admirable fac-simile reproductions of ancient M.S.S. as to give to the student at his own table facilities for investigation and comparison obtained before only by personal visits to the museums and libraries of Europe where the originals are preserved.

"Three smaller presses were turning out copies of coins—one for an illustration to the annual report of the Royal Mint, another a series of Asiatic coins for the *Numismatic Chronicle*, and a third for a history of the coins of Cromwell and the Commonwealth. These representations obtained from coins (or, perhaps, casts of the coins) were simply superb—the revelation of a new art! The boldness of relief and the clearness of detail made the photographic image almost equal in instruction to sight of the coins themselves. I was not surprised, after examining the work that the Company had illustrated—costly books on Greek, Roman, Syracusan, Mahomedan, Scotch, and Swiss coins—that a steady rill of business flowed towards the Collotype process in this line alone.

"There was also in every stage of execution, from the careful preparation of the negative to the storing completed prints, an elaborate series of photographic illustrations of spectrum analysis; and another series of enlargements from microscopic negatives being printed to embellish and enhance the value of a work on the Rocks of Queensland and Australia. Further up the room no less than four presses were at work on a series of fifty-four plates to illustrate a learned work on Fossil Botany. These were copies of elaborate drawings, to which photography alone could do adequate justice. The edition commanded was one thousand

copies of each of the fifty-four plates, and this alone made an item quite 'commercial' in its amount.

"Another large commission in course of active completion for, I imagine, a foreign government, was a series of about sixteen by thirteen photographs of public works, viaducts, lighthouses, railway stations, docks, fortresses, and the like. I saw hundreds of separate illustrations, and evidence enough that a job was in hand mounting up into serious figures. It would be scarcely fair for me to enumerate all the items of work of which I was permitted to take one, but I was struck by the preponderance of scientific and artistic work, and the comparative absence of work from negatives direct from nature. The public works mentioned are, of course, an exception on a large scale; but I saw scarcely any portraits, and but few landscape views. It is questionable if Collotype lends itself to the multiplication of cartes-de-visite, &c., so readily as the Woodbury process, but it was self-evident, not only that Collotype printing has an extensive field of operation, but that it has taken possession of that field to a great extent. I found a numerous staff, some forty persons in this department alone, and their weekly wages would scarcely continue if the depreciatory estimate of this branch of the black art were the true one.

"I gathered clearly into my mind during the visit that the commercial success of Collotype depended mainly on the ability of the staff to cope with chemical and mechanical difficulties as they arise, and to give to every detail of the process an intelligent and scrupulous care."

UNDRAPED INNOCENTS.*

ALONGSIDE the photographs of persons known to fame, as arrayed in the stores where such portraits are sold, may be seen the picture of a nude, pretty little child, probably about two years old. Its chubby body is represented lying on a cloth, the folds of which cover it to a slight extent. The picture is an attractive one; the infancy of the child being a bar to any idea of indecency, and women admire and buy it extensively. The photographer who put it on the market said, when asked who the child was: "Oh! I wouldn't dare to tell you, except as a secret not to be published. The parents brought her—it's a little girl—to be photographed in that way, and when the picture was made I saw at once that it was pretty enough to sell in the market. So I asked permission to duplicate it. At first the mother refused, but at last she consented, on my promise not to divulge the identity. The truth is she was proud of her offspring's beauty, and hankered after the admiration that the picture would excite. I am selling copies by the thousand, for I am supplying dealers throughout the whole country. All parents, however, could not be brought to consent. I know a photographer who sold pictures of a little son of a gentleman of Newark, and he threatened a lawsuit in consequence. Another case was that of the President of a Life Insurance Company. He had a wonderfully beautiful daughter, about four years old, whose picture was taken by a New York photographer, and a really attractive picture it made. The photographer duplicated it for the trade. Those who have paid much attention to photographs in the stores will remember it—a plump, round-eyed child, coquettishly dressed, and sitting with negligent grace on a sofa, with one of her dimpled legs hanging down. This picture was selling fast, when the father learned about it, and forbade any further sale. All that could be got were called in from the stores. In this case the child was clothed."

"You speak as though pictures of unclothed children are common," said the reporter. "Such is the fact," was the reply; "there seems to be a rage for it just now. Every photographer in the city is doing more or less of such work now-a-days, and very acceptable they find it, I can tell you, in this dull season."

The reporter, in quest of information as to this new

* *New York Mercury.*

feminine freak, called on several of the most fashionable photographers. They all freely acknowledged the surprising extent of the new feature in their business. Naturally, they could see no harm in gratifying a mother's desire to preserve a reminder of her child's infantile charms. Said one:—"I suppose I have made photographs of twenty nude children within a month. It seems to be a wholly new idea, and has suddenly become the rage. These children were from one to four years old, perhaps a little older in one or two instances. Generally the mothers have a settled idea about the pose that they desire, which is often an imitation of some familiar sculptured or painted figure. Cupid is, as might be expected, the model that many expect, and the little ones are made to assume attitudes before the camera such as are given to him in art. I'll show you some of the pictures." Thereupon he took a small album from a drawer, and displayed its contents, consisting of about half a hundred photographs of the kind in question. He said that he kept them as samples, from which patrons might select styles. Cupids abounded, and in several instances statuary was so well imitated in pose that it was hard to believe the original was not marble instead of flesh. Cherubs of various sorts were there, too, and one plump little fellow had wings stuck on his shoulders. A fair, six-year-old girl was posed as Power's "Greek Slave," showing a form as perfect in childish grace as the statue is in womanly beauty. A shapely baby lay in a large shell asleep, and another was kicking up its legs, and flinging its arms as though in high glee.

The chief operator in a leading Broadway establishment said:—"It's the most natural thing in the world for parents to want to preserve in pictures the beauty that is bound to pass away in their children. Why, I have photographed nude the baby of a prominent clergyman, and all my patrons in that peculiar line have been of a cultured, fashionable class." This operator said he had an engagement to photograph four children in a group, and he believed that some painting was to be imitated in the poses. Indeed, it was a peculiarity of this business that the mothers almost always came with a settled conviction of how they wished their darlings to sit or stand. They usually have discovered a likeness between their children's forms and some work of art, and that is enough to decide their choice. He showed the reporter a negative which he had been "touching up," in which a slender, beautifully modelled girl, apparently about five years old, represented Aphrodite rising from the sea. A background had been painted in imitation of a picture that attracted much attention in the Centennial Exhibition, and the figure was graceful enough not to suffer by a recollection of the original. The girl must have been carefully trained both as to her attitude and her expression of face. Indeed, most of the pictures that the reporter saw bore evidence of drilling in the little ones whose forms had been exposed to the camera.

Correspondence.

ALKALINE DEVELOPMENT WITHOUT PYRO-GALLIC ACID FOR DRY PLATES.

Sir,—My plates are eighteen by sixteen; I have a tin dish sufficiently large for the plates, one and a-half inches deep; the inside of the dish has had several coats of white paint, which answers admirably both for developing and washing the plates. In preparing to develop, I pour into the dish as much tap water as will fill the dish to about half an inch deep, then drop into the water about twenty drops of strong liquor ammonia, rock the water about to mix it with the ammonia, then take the plate from the dark slide and place it in the dish, collodion side up, taking

care to flow the water over at one wash, to prevent developing lines. The image will appear immediately. It is as well to rock the dish to cause the water to wash off the preservative at the same time. The same water will develop two or more plates, if used at once. Wash and intensify with acid silver and pyro. If fully exposed, very little intensification will be required. I can easily finish one while the other is left in the water.

REUBEN MITCHELL.

VALUE OF ALCOHOLIC WASHING FOR EMULSION OR PELLICLE.

Sir,—I think you will find that you have in your last issue given credit to the wrong person (Mr. Wratten) for originally discovering the above. I find it was announced (and I believe first) by Colonel Stuart Wortley to the Photographic Society (see PHOTOGRAPHIC NEWS, June 30th, 1876); thus:—"When the pellicle is set in the dish into which it has been poured, it is cut up with a clean slip of glass, and put into a bottle; it is then rapidly rinsed with three or four changes of distilled water, and then with two changes of methylated alcohol, in the latter of which it is allowed to soak for a quarter of an hour. It may then either be taken, and, after blotting off the superfluous moisture, be dried by a gentle heat, or it may be left in a bottle with clean alcohol, which I find to be by far the best method of preserving sensitive gelatine pellicle; and under any circumstances, washings of alcohol are most important, as they extract all the water (this is the point) from the gelatine, and render it far easier to thoroughly dry the pellicle. I also find the diluted alcohol useful in the preparation of the collodion pellicle; but I need hardly point out that in that case it must not be used too strong, or it will cause partial solution."—Yours faithfully,

Junior United Service Club.

HERBERT KERR.

[It will be readily seen, we think, that there is a difference between the two methods and the two aims.—ED.]

Talk in the Studio.

GUM FOR RETOUCHING.—A discussion has been going on in the *Practical Photographer* (St. Louis) on the advantages and disadvantages of a gum surface on negatives for retouching. Amongst the disadvantages is found the fact that cockroaches, being fond of gum, attack the coating, and fail to discriminate between the gum coating and collodion film, eating up all together; the portrait of an emperor or of the most beautiful woman serving merely as a meal for a cockroach.

YELLOW LIGHT.—Mr. Robert Charles Croft writes as follows to the *Daily News* on the above subject:—"It has given me much gratification to find that the humble suggestion I made through your columns respecting 'the application of yellow light as a remedial agent' has met with so much attention, both from the public and from scientific men, although the latter seem disposed to cavil because they cannot at present reconcile their theoretical knowledge of light to the practical use I have suggested. One gentleman under the signature of 'Watson Smith, F.C.S.' is so emphatic upon the matter that I beg permission to say a few words in answer. This correspondent gives me credit for advising yellow light in smallpox, but says that I 'seriously go out of my way' in making other suggestions; that it is a pity I did not try the effect of yellow spectacles (taking it for granted that I did not do so) before I wrote the letter suggesting their use and the use of yellow veils for inflamed eyes and sunburns; and he goes on not only to depreciate yellow light, but to advise your 'lady readers,' before adopting it, to read his elaborate description of the composition of light, and 'to judge for themselves' whether afterwards they will wear blue or yellow. All this is very well, sir, but very little to the purpose. The letter is admirably written, and the description of the spectrum clever enough; indeed, I fancy it is almost too clever to interest the fair readers whom he addresses. Let me in my turn state one or two facts. I am writing this letter in the glaring sunlight, wearing spec-

lenses over which I have placed a piece of deep yellow glass, and I am writing in the greatest comfort, whilst if I remove the yellow glass the glare is too painful to endure. Thus protected I have just been out in the garden and can look up straight at the sun without the least inconvenience. Any one can try this plan (yellow spectacles cannot yet be had), and if it be found that by using some yellow medium we can endure more glare and derive more comfort than we can obtain by any other means, surely it is best to try the practical experiments first and to theorise afterwards. As regards the use of blue spectacles, they relieve for a few moments, but the eyes almost always feel peculiarly uncomfortable after they have been worn for some little time. Perhaps I may be allowed to put the case before your fair readers in a less learned and more familiar manner. Light possesses three properties:—1. Illuminating power; 2. Heating power; 3. Chemical power. You can certainly separate the chemical power from the others, or the photographer's 'occupation would be gone,' for light filtered through a yellow medium, although it retains its illuminating power, loses its chemical properties, and the sensitive plates are not affected. Now what I want ascertained by experiment is this: Can the three properties of light named above be separated or combined and used in any way as agents, to cure disease or to alleviate suffering? I quite believe this to be possible, but as one man can only hope to get together a very small amount of experimental knowledge, I have elected to make public what little I know, in the hope that others will assist in ascertaining any facts connected therewith, and I make this public with less hesitation, seeing that it involves no question of medical treatment, but is an experiment so simple and inexpensive that if there be no ultimate benefit gained, at least no harm will result. The letters I continue to receive relating the temporal effects of yellow light in special cases are encouraging, and I hope the subject will not be lost sight of." Our readers will remember that a correspondent last week gave his experience with a pair of yellow glasses constructed by himself.

RETOUCHING SURFACE.—Mr. C. Ferrie, in the *Practical Photographer*, gives the following:—"Dissolve one ounce of common brown dextrine in sixteen ounces of boiling soft water; then add fifteen grains bichromate of potash; when dissolved, filter, and it is ready for use. Rinse your negative thoroughly from the hypo. fixing solution, and flow with the dextrine; varnish and set away from dust to dry, when it should look as if dried in the usual way without any preparation. If it looks the least glossy, your dextrine solution is too thick and must be reduced. Hand one of these plates to a retoucher, and he will avoid touching it with a pencil for fear of scratching. But there is no danger; it will stand a pretty heavy hand with a XXX Faber pencil, and is capable of taking any shade from the lightest to perfect opacity; and for those who are in favour of needle stippling it leaves nothing to be desired, as it will neither chip or flake off. When you have retouched to your liking, rinse thoroughly under the faucet, dry, and varnish; or, if but few prints are wanted, you need not rinse or varnish."

To Correspondents.

M. Y. F.—If you carefully follow the instructions in any of the articles to which you refer, you can scarcely fail to succeed, but you must be precise in following instructions. The water running irregularly over the face of the Daguerrotype when first applied does at times cause some trouble. When we have found a tendency of this kind, we have applied strong alcohol first, to remove any trace of greasiness which may be present if the plate has been taken from under the glass and fingered; then wash thoroughly with water before applying the cyanide solution. Do not attempt to use a strong solution of cyanide, as if it be too strong it may dissolve and destroy the image.

BAKINER.—You have applied the cyanide fixing solution immediately after development without washing the plate between the operations, and the combination of the iron salt and the cyanide has produced Prussian blue. Remember that you always wash the plate between development and fixing. 2. The image appearing gray all over, and flat looking, may be due to many causes; but most probably, in the case you describe, the defect is due to either over-exposure or over-development. In producing collodion positives the development should be very rapidly done, so as to avoid any deposit on the deep shadows, but for negatives development may be much more deliberate. We prefer backing with maroon velvet; it gives, we think, a richer effect than black varnish.

A. SHORTLAND WRITER.—The primary cause of your imperfect toning is one to which we have very repeatedly of late called attention—the use of a thin poor negative. It is impossible to get rich, vigorous prints from thin, poor negatives. There is not in the deepest shadows of your print a sufficiently deep deposit of silver in printing to receive a rich tone in the gold bath. The negative has apparently been produced in a dull diffused light which has not given a sufficiently marked light and shadow to yield a vigorous image. When the negative lacks intensity and vigour, the lights print through before sufficient silver is reduced in the blacks, and the weak print which is placed in the toning bath only acquires a lavender, a drab or a gray tint, instead of a rich purple-brown or black. The print you enclose is only weak, not unweary. Mediocrity presents a grey-looking granulation. It is generally due to the use of the toning bath too soon after it is mixed. Very long washing before toning makes the toning operation somewhat slower. But whilst prolonged washing is not necessary, the washing must be thorough. The irregular toning of which you speak is probably due to irregular washing previously.

DILKINA.—Judging from the appearance of your print, we should have concluded that the negative had been scratched, and that the chemicals were working very well. We can see nothing in the formula which should not give a good bath. It is rather strong, and we should think not fully iodized. The thin images we should attribute to using a new collodion, as you say you are doing. Use a ripper collodion, and probably matters will improve. As for a formula for a bath, we never find that one made with thirty grains of ordinary crystallized nitrate of silver to each ounce of pure distilled water fails. We generally add from one to two grains of iodide of potassium to each pint of solution. If you have any difficulty, some of the photographic chemists will supply a bath in working order. Mr. Thomas, of Pall Mall, will, for instance. 2. The surroundings to the portraits in question are produced by double printing. We do not think you can buy the negatives for the purpose. As a rule, each photographer designs and photographs his own fancy negatives. Mr. R. G. Payne, of Aylesbury, we believe, supplies a few negatives for ornamental outsize. Possibly he can oblige you.

B. L. A.—It is a moot point whether plain paper prints or albumenized prints are most permanent. Some investigators are disposed to attribute fading chiefly to albumen, but it is quite certain that plain prints do not possess any certain immunity from fading. Developed prints, produced with care, and properly kept, have generally been found to stand well, and have, in most cases, escaped fading. Fading was at one time chiefly attributed to the use of the old hypo and gold toning bath, by which a mixture of gold and sulphur toning was produced, but some toned in this way remain without fading until the present day, having been produced upwards of twenty years ago.

M. Y. S.—If a print be carefully produced—that is, properly fixed with fresh hypo, and then well washed—we think that its permanency is unquestionably made more certain by enamelling or coating with collodion, but if fixation be not properly carried out, sealing the picture up is only sealing up the elements of decay in it. Nevertheless, the general effect of enamelling is, we think, beneficial.

J. HENRY WATKINSON.—Many thanks. The gentleman to whom you refer does, we believe, work the wet process, and your photograph from a collodion plate is unquestionably a finer picture: a powerful argument for the process; but something may be due to the workman!

SLAVE.—Fogging in opal prints may be due to many causes. The same formula and materials which will produce a good negative are not necessarily suitable for opals. The bath may possibly require a little more nitric acid, or the developer may be too strong or insufficiently acid; or the exposure may be too long; or—this is most probable—the development has been too much prolonged.

ONE WHO TRIES.—We have not tried the formula to which you refer. Our experience is antagonistic to the use of acetate of silver in the negative bath. 2. See Mr. Dallmeyer's letter, page 361 of our last issue. 3. A weak solution of iron with citric acid answers the purpose well.

A. LEARNER.—The prints you enclose are not perfectly fixed. The hypo has been old and exhausted, or over weak, or the prints have not been perfectly immersed. 2. We do not quite understand your trouble described as creasing in the background.

F. M. BUTCHER.—Thanks. We shall probably say something on the subject shortly.

RUBEN.—We do not clearly understand what it is you wish to register. Is it the style and mode of grouping? If so, it must be registered under the Design Act. As it has never come within our province to effect such a registration, we cannot direct you with advantage. A patent agent will help you. But we should tell you that a similar mode of grouping in photography has been practiced before.

H. G.—We do not remember the drying box you mention. Several Correspondents in our next.

The Photographic News, August 31, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

THE PARIS INTERNATIONAL EXHIBITION—POISONING IN THE PHOTOGRAPHIC LABORATORY—THE WARNERKE FILM FOR TRANSPARENCIES.

The Paris International Exhibition.—If North Germany has officially refused to support the Paris International Exhibition for 1878, it is not so with Austro-Hungary. To judge by the names of intending exhibitors which have already been received for Class XII., from Vienna alone, we may expect a very fine show of photography and photographic requisites. No less than half a hundred gentlemen connected with photography, and residing in the South German capital, have signified their intention of forwarding contributions, and other cities of the same State, Trieste, Salzburg, Luiz, &c., will be well represented. In fact, everything seems to augur well for the next French International Exhibition. From France there will be as many as 280 firms represented in the sphere of photography, and, although we cannot state positively the number of British photographers likely to exhibit, we know of several eminent houses who have resolved so to do. Mr. Cunliffe Owen, to whom the whole business, so far as it concerns Great Britain, has been entrusted, has already established himself in Paris with a large staff, all of whom have found plenty to do for some time past. In fact, the circumstance that the Prince of Wales is not an honorary, but working, president of the British Commission proves of itself that the matter, so far as this country is concerned, will be carried out with spirit. The Prince does not shirk his work, but is continually holding business meetings at which he presides, and has more than once visited Paris with a view to furthering the functions of the British Commission in that capital. Notwithstanding, therefore, the gloomy state of things in the East, there is every prospect of Paris presenting next year one of the most brilliant of exhibitions that have ever been held. That a gathering of this kind in Paris is sure to be attractive there is little room for doubt, since everybody is only too glad for an excuse to visit the French capital, while it is more favourably situated than any other spot in Europe. Not only is it adjacent to all the western nations of the Continent, but it is convenient, too, for our cousins on the other side of the water.

Poisoning in the Photographic Laboratory.—At Dusseldorf, the other day, a melancholy accident happened to a photographer, who swallowed some cyanide of potassium by mistake. It appears that he was a travelling photographer, and after a hard day's work wished to take a little brandy from a bottle that was among his utensils. It was dark at the time, and by mistake he took up a bottle containing cyanide of potassium instead, and drank off a draught before he discovered his mistake. The result was almost inevitable. Before aid could come, the virulent poison had done its work, and the man was a corpse. The sad tale carries a stern lesson with it, which those who have a loose way of keeping their poisons will do well to profit by. Almost similar catastrophe happened in our presence in a laboratory in this country not many years ago. In this case a man had some cyanide of potassium solution in a bottle which he kept for cleaning silver. The bottle, to be out of harm's way, was kept locked up in a cupboard, and all went well for a time. But one day the man was given some medicine to take, and this also, after he had swallowed a dose, he put into his cupboard. The next time the poor fellow mistook the bottles; they were in shape both alike, and the liquid therein was not so very different. He poured out a dose and swallowed it, and three minutes afterwards he fell down insensible, with his teeth firmly

clenched. He had been told to take his medicine just before meals, so that the poison acted at once upon the empty stomach. As most people know, the best thing under such circumstances is to swallow an emetic or to take chlorine water or solution of iron, but in the case we speak of, unfortunately, none of these remedies could be supplied with sufficient promptness. Within a quarter of an hour of the event, a stomach-pump was forthcoming, the best thing to use in all such cases, but the man's jaws were so firmly closed that some time elapsed before they could be opened. In the meantime the man was a corpse, and all worldly aid was without avail. One thing these accidents teach us, which should not be lost sight of: it is, that no poison should be contained in a bottle of the ordinary shape and form. Labels are of little use, for in the Dusseldorf instance the man took up the bottle in the dark. But, as everybody knows, there are such things as poison bottles made, different in shape to ordinary vessels, and of these all who have to deal with poisons should keep a stock. If a photographer employs cyanide of potassium daily for fixing, as we presume was the case with the Dusseldorf photographer, he could always manage to secure it in a differently shaped bottle to others in his laboratory; and furnished, moreover, with a label with the word "poison" on it, there should be little risk of accident in the dark or light. "Familiarity breeds contempt," unfortunately, and the consequence is, that having to do every day in his life with poisons more or less virulent, the photographer looks upon them much in the same way as he does his bread and butter. Many, we know, have given up the use of cyanide almost completely, but, nevertheless, it is difficult to do without it altogether, in one operation or the other. On the other hand, in many studios this acute poison is very loosely looked after, and, we fear, is frequently left where ignorant fingers can touch it. So dangerous and rapid is its action when taken internally, that, as we have seen, there is little hope for the sufferer, and it is a mistake to suppose that only in the event of swallowing the compound its workings are deadly. It is not so long ago that we announced in these columns the death of an individual who employed cyanide of potassium for cleaning his fingers, and who had rubbed some of the salt into an abrasion of the skin. Such a case may be rare, but the partial paralysis of the hand and fingers from rubbing cyanide upon the skin is by no means so. We earnestly conjure our readers, and especially amateurs, who are given to the use of cyanide, to take proper care of this terrible agent, and whenever a solution of it is prepared for ordinary use, to put it into a vessel at once distinguishable from those in ordinary employment.

The Warnerke Film for Transparencies.—It is a well-known axiom in dry-plate photography that you cannot over-expose. If twenty seconds will give you a picture, so will forty and sixty, if you will only use a development suitable for the occasion. One instance has recently come under our notice which affords at a glance how far, indeed, one may expose without injury. Mr. Woodbury, whose charming and delicate transparencies are very generally known, recently found that some carbon tissue he had by him failed, in a measure, to give such a result as he desired, and he thereupon essayed some emulsion tissue of Mr. Warnerke for the purpose. The tissue was put into a printing frame upon a negative, and exposed in this way to direct light. Instead of doing this for but a second or two, which would certainly have sufficed, Mr. Woodbury permitted an exposure of one minute and a-half, and then forwarded the film to Mr. Warnerke for development. The images by this time were as plainly marked upon the tissue as if they were albumenized prints, but by careful development they yielded transparencies of a delicacy and vigour not to be surpassed. In a word, we may frankly say that we have never seen better transparent positives than this over-exposed tissue in the end yielded.

PHOTOGRAPHING STATUARY IN AN EXHIBITION.

Mr. JOHN L. GIBSON, manager of the photographic operations in the late Philadelphia Exhibition, in some "Rambling Remarks," describes in our Philadelphia contemporary, some experiences with statuary. He says:—

"There might be quite a good sized volume written in regard to the photographing of those marbles. Now that it is all over, I have my own little secret laugh at my comical experiences. To give a partial explanation—for I won't give the whole of it—I will say that certain parties, generally Italians, calling themselves either artists or agents, had the care of these figures.

"They made arrangements with the 'Company' for the production and sale of photographs of attractive subjects.

"Some of the aforesaid 'artists and agents' had desirable models, others did not. Naturally, jealousies soon came into birth, and those who had little to represent them, or may be, more properly, who had, began to give us trouble, and seriously impede our workings. This opposition was carried to such an extent that toward the closing of the Exposition we were not allowed to work in the art galleries after half-past eight o'clock a.m. Now, gentlemen, those of you who are disposed to do so, and who most certainly do indulge in the habit of criticism, bear this fact in mind. Messrs. Wilson and Adams paid large amounts of money for the privilege of making pictures of some desirable figures. The commissions were, of course, transferred to us who operated. There was no opportunity to move those heavy stones from place to place, and having to work almost at the dawn of day, there was surely not much chance to choose the light. If people—those who pick up a picture, and give it sometimes an adverse criticism—were to know anything of the difficulties under which it had been made, they would be, at least, more lenient in their expressions. Many are the wordy fights that I have had with those 'Sons of fair Italy.' A disinterested American or English observer would have supposed on some occasions that assassination was imminent. I know the character of the people much better. 'Bluster and gesticulation' are sufficiently expressive terms to give character to their actions.

"If you feel at all like myself, you will excuse the inclination I evince to get out of the hard-trodden path of photographic literature.

"Formulæ are being constantly printed and reprinted that are as old as the art itself. Reports of scientific investigations about peculiar properties of rays of light and certain characteristics of subtle chemical compounds (never used by the average photographer) consume as much space as I demand for my R's.

"Picking up my third R, and resuming, I must tell you of our method of varnishing and preparing negatives for printing purposes.

"Since our time for operating upon the statues was reduced to such a minimum, and since we required so many negatives of some of them, we used to put all of our available force at the work, and during a clear morning, an outsider, dropping into one of the art galleries, might have been excused for supposing it to be a photographic stock depot. There were certainly, on many occasions, more instruments than there were models. It was often the case that five cameras would be pointing towards the one subject. As some of these would have four lenses glaring from their fronts, you can readily imagine that a good many negatives were made, even although the circumstances were adverse. It was no unusual sight to see twenty or more instruments being worked simultaneously in one apartment.

"It seems to have become the favoured style to have photographs of statuary prepared with an intensely black background. That I, myself, do not give sanction to it is of very little consequence. I was obliged to accept the idea and aid in its practical production.

"At first, when there was plenty of time, and when one

was allowed the privilege of a full day's work, it was the custom to erect temporary backgrounds, or screens made of very heavy, very dark-green baize. The contrast between the whites of the marble and the heavy colour of the drapery were sufficiently great to give a transparent film in the rear of the figure.

"When we had to rush matters, pop away with all the instruments in our possession, it became impracticable to put up these backgrounds. It would have required as extensive a supply of material as any of the cycloramas demand. Other methods had to be adopted. The most efficacious was to scratch away the background, leaving a bare glass surface, before varnishing the negative. To do this, a considerable amount of care, and some skill as well, is required in following around the outlines of the subject. The major portion can be quite readily removed with a piece of chamois skin moistened with alcohol and ether, or even with alcohol only.

"I originated a style of picture adapted to the reproduction of statuary, the making of which I am sorry to see has not been more vigorously prosecuted. The invention consisted in printing upon the finished albumen print a lithographic background. My design was to secure, or rather retain, all of the delicacy of the silver impression, and then to enhance its value by the contrast of either a flat, or, as the artist terms it, a dead surface, or otherwise an imitation of drapery in subdued colours. Even a flat, gold, silvered, or bronzed relief could be obtained.

"The process is only suitable for such establishments as that of the 'Centennial Photographic Company's,' where immense amount of prints from each negative are made.

"To consummate it, a good deal of detail has to be entered into. No matter how closely they resemble each other, the prints from different negatives have to be kept scrupulously separated. Then again they have to be printed with registered marks, in order to guide the lithographer in his work. One other drawback, I acknowledge, is the tendency of albumen paper to either expand or contract in the most unexpected manner. (One never knows, in the case of a large picture, whether a face will be made an eighth, aye, even a quarter, of an inch longer or broader than he intended it to be. At the last meeting of the members of the National Photographic Association, Mr. W. Curtis Taylor gave quite an interesting discourse upon this subject, and his remarks were responded to by a desultory discussion. As I remember it, the only conclusion arrived at was that sometimes paper would contract, and at others it would expand, and that generally it would do so in directions contrary to your desires. The whole argument was closed by laying the interesting specimens with which he illustrated his lecture (photographs of Dom Pedro) and the discussion generally, in parliamentary phrase, 'upon the table.' The only practical part of the whole affair consisted in the leaving of the pictures to the disposal of the Association.

"Resuming again (I am fond of the letter R.), I will remark that this pet style of picture, which I most certainly claim to be an origination of my own, has been basely imitated. Passing along our leading street in this Quaker town, and adhering to the custom which I acquired in childhood, of looking into every window that contained a picture, I discovered a good many representations of all kinds of differently proportioned Venuses, Apollos, Cupids, and Psyches, that were gotten up or about the same principle. In these instances, however, the picture itself—that is, of the statue—had been carefully cut out from its surroundings, probably with scissors, may be with a 'Robinson Trimmer,' and pasted upon a black or chocolate-coloured cardboard. Although furiously indignant (?) at such an innovation upon that which I claimed to have been an original design, I will acknowledge the effects to be good.

"It is in place here to advert to some pictures that the most of you must have seen, because they were on exhibition in Photographic Hall during the Centennial season. They were also copies of marble and plaster work, mostly of

baso-relieves. I believe that the manner of their production has become the origin of another patent. Looking them over I found that the photograph of a statue was carefully cut out and sealed to a glass. Then the plate was silvered in such a way as to represent a mirror. Putting the affair into the plainest words that I can use, the result seemed to be the combination of a photograph and looking-glass. I liked them so well that I was about to commence making them when I was deterred by that terrible warning against 'infringement.'

"Let us drop the talk about the marbles, or rather the statuary, get back into the orthodox recitation of photographic processes, and consider the varnishing of the negatives. There was a cosy little room dedicated to the purpose. It was surrounded by shelves, and upon these the plates were first placed when brought into the establishment. In one corner there was a veritable closet—no other term would describe the contrivance. It also had shelves. They were made, though, of wire. A gas-stove was placed at the bottom of the cupboard, and when lighted, the heat from it would very soon work its way through the partitions, and speedily dry anything placed upon them.

"Once dry, the negatives had to be varnished; and now commences the resumé of many a trouble.

"Every make of varnish was experimented with. I remember reading at various times during a period of some years, in the English journals devoted to photography, the laments of operators who constantly spoiled their negatives in the varnishing process.

"Lately, since I have been again established in business, I have had instances of valuable plates being destroyed by impure coatings.

"My preferences incline me to the use of a composition made almost exclusively with alcohol and gum sandarac. A small addition of oil of lavender does no harm. I am not convinced that it does further good than to change the smell of the other composition. Castor oil is claimed to be a valuable ingredient, but I acknowledge that I have not made sufficient experiments upon which to found an opinion.

"Without in any way deprecating the manufactured article furnished by the stock houses, I must say that our preferences finally induced the use of a varnish prepared by Mr. Hopkins. I believe that he intended to introduce it to the trade as a staple article, so I have not presumed to ask him for its composition.

"If the varnish is good, I don't know that anything especially can be said in regard to the manner of using it. Experience alone teaches one how to handle a plate, and the workman is no workman after all who depends upon his success on the following up of printed instructions. It is impossible to flow a plate well that is too hot; it is equally impracticable to coat one that is too cold. You cannot very conveniently gauge the condition of a negative by any thermometrical instrument. You must depend upon your fingers, your sense of touch, as your guide. As I have already intimated, practice and experience are the only rules by which to work.

"Sometimes it is advisable, even necessary, to remove a preliminary coating of varnish, and to apply a second. This operation also necessitates a little care, as does everything in connection with the photographic business. A good many methods have been suggested, but I know of none more speedy than to flow the plate with alcohol containing what you might term an impregnation of cyanide of potassium.

"In doing anything of this kind you have to keep a sharp look-out. I have seen exceptional instances of collodion films having been destroyed and washed away from the plates before a stream of water could counteract the influence of the agents used for cleansing purposes.

"The defective varnishing of a negative will create an immense deal of after-trouble. If the fluid is not smoothly flowed, the lines occasioned by its irregularity in drying will most certainly show upon the print. If the plate is heated

over a spirit-lamp, and, through inadvertence, a little conflagration takes place, then spots and blemishes are bound to be the almost irremediable results.

"Adverting again more exclusively to the doings of 'the Company,' I must state that one young gentleman had his time almost exclusively occupied by this varnishing of negatives.

"Some days each one of us who operated would bring in several box-loads. As there were a number of squads of active workers the aggregated accumulation would occasionally be appalling—at least to any one who desired to make early hours. You must remember that negatives were not 'turned over' until almost dusk, and it would never do to allow the work of one day to lay over for completion to the next.

"Assuming that the negative had been successfully varnished, and thus secured from chances of ordinary accident, it still remained for more to be done to it, previous to its consignment to the printing department.

"Our ordinary term for this next operation was 'the shaping.' Retouching was in but little demand, since the major part of the work was of landscape subjects, and the negatives were required to be sufficiently perfect to dispense with it.

"The 'shaping' was a matter of sufficient importance to justify me in making it the basis of another article."

SOME FORMULÆ.

An intelligent correspondent of the *St. Louis Practical Photographer*, writing under the signature of "Little Carbon," gives some details of formulæ worth reproducing. He commences by condemning the use of strong toning baths. He says:—

"In your Bureau of Information, page 227, is a German formula, in which the toning bath contains half a grain of chloride of gold to each fluid ounce. I would characterize this as a horrible bath. If the German artists use such a toning bath as this, it is no wonder they asked H. Roeder, of Chicago, for his formulæ. According to my experience, it would tone so fast that it would take half a day to tone a fair day's printing, and it would be impossible to produce a batch of prints any way near an even or uniform tone. Why? Simply because it is about eight times as strong as it ought to be, and about twenty times as strong as some of our best printers use. I formerly used one grain of gold to sixteen fluid ounces of bath, and my prints toned so fast I could not manage more than six or eight at a time. When I visited Chicago, in '74, I was surprised and delighted with their brilliant tones. Being known as one of the old fogies from the Daguerrotype times, I was at once admitted behind the scenes, and, to my intense surprise, I found men toning with from fifty to one hundred prints in the bath at once. I looked on in amazement, expecting to see some prints reach the old blue-black tone before they could be got out of such a mass; but no such thing occurred. The reason was the prints required from fifteen to twenty-five or thirty minutes to tone, and the tones were beautifully uniform. I remember when I published the albumen process in '61 to have stated that one grain of gold was sufficient for a sheet of paper. When the Journal was received in Rochester, N. Y., where I then was, the leading operator called on me and swore roundly I was a fool or a liar, he did not know which, because his experience taught him that a sheet of albumen paper required three grains of gold. In 1874 I called on the same artist, now doing a splendid business in Detroit, Mich. I asked how much gold he used now? He replied, that his toner calculated one grain of gold for one hundred card prints, or about one grain to three sheets, as it is usually cut. Try to precipitate nitrate of silver with a strong solution of chloride of sodium, and notice the grossness of the precipitate; next take some of the same silver solution and add a weak solution of chloride, and notice

the result—the precipitate will be fine. Or try to do silver-plating with a strong cyanide solution: the result will be rapid coating, but it will flake off; whereas if the coating is done in a weak bath, it will work slow but sure, and will be as firm as if it were not plated, but solid metal.

"As I do not believe in denouncing any formula without offering what I conceive to be a better, I will here give one that has stood the test of ten years' every-day practice:—

"*Silvering Solution.*—Soft water one ounce, nitrate of silver forty grains; float from thirty seconds to two minutes, according to temperature and the requirements of the particular sample of paper in use; when dry, fume until it prints a rich purple black, slightly bronzing in the deep shadows, say fifteen minutes as an average; wash in four changes of water, no acid, but to the fourth water add sufficient salt to make the prints decidedly red. This salt has a double effect: first, the red colour it gives the print enables the toner to decide at once when the colour he wants is reached; second, and most important, it changes any free nitrate which the washing has left in the prints into chloride, a very important item, because a very little free nitrate will precipitate the gold from the toning bath. Soft water for the first washing is also important; if water containing lime—commonly known as hard water—is used, a scum of chloride of silver is apt to form on the surface, which colours with great rapidity in the toning bath, often leading the novice to suppose his print over-toned, while really scarcely begun. Consequence, when immersed in the soda, it is instantly dissolved, leaving the blue-black print brick-red. I make my own chloride of gold by dissolving 25 grains dentist's waste gold in acid nitric C. P. 60 minims, acid muriatic C. P. 120 minims. This will give a solution of which you know the exact value. Dilute to 12½ ounces with soft water. If the acid does not dissolve all the gold, add more until the gold is entirely taken up, but in diluting keep it to 12½ fluid ounces. This gives a solution containing two grains of gold per ounce. Take of this solution a quarter of a fluid ounce, equal to half a grain gold, soft water 16 ounces; neutralize with a saturated solution of bicarbonate of soda, and use at once. Washing soda will do, but I prefer the bicarbonate. Any required tone can be obtained with this bath, from blue-black to chocolate brown, which is at present a very popular tint. Do not throw away the bath when used, but when next wanted decant the clear liquid, leaving the precipitate in the bottle. Add gold from the stock solution, and neutralize. Fix in hypo one part, water six to eight parts, keep moving for fifteen to twenty minutes, then wash.

"*Development.*—I will also give a developer, not because it is so much better than any other, but because I make it 'different from white folks.' Take a wide-mouthed quart bottle (a fruit jar answers well), make a bag of very coarse muslin (Swiss double is first rate) large enough to hold eight ounces prot. sulph. iron, weigh your iron and put it in the bag; now let the bag into the mouth of the bottle, and with a rubber band fasten it so that the iron will remain just even with the top of the bottle; fill up with soft water, and set it aside while you go on with other business; by-and-by you will find the bag empty, and the iron all gone to the bottom; stir it up and spread the bag over the mouth of the bottle to keep out dust. This is the stock solution, and contains a quarter of an ounce of iron to each fluid ounce. For ordinary use, take—

Stock solution	4 ounces
Soft water	12 "
Acetic acid No. 8	1½ "
Alcohol	½ ounce.

This gives a developer of twenty-four grains per ounce. For redeveloper take of—

Stock solution	1 ounce
Citric acid	½ "
Water	15 ounces

Grind the citric acid in a mortar with a little water, and add to the iron, then fill up with the rest of the water.

(Of course every photographer knows that a little silver must be added to the re-developer before using.) So water must be used. If hard water is used, the silver of the plate is instantly changed to chloride, and development ceases, giving thin, worthless negatives, where first class negatives might as easily be obtained. With the stock solution I can mix a pint or quart of developer in two minutes—strong or weak as circumstances require. Take a bottle that will hold twenty ounces fluid measure, cut a strip of white paper half an inch wide, and long enough to reach the top, paste this on the side of the bottle, and when dry measure four ounces of water into the bottle, and on the paper mark its surface, repeat and mark at 12, 16, 17, 18, 19, and 20 ounces; varnish this paper with negative or positive varnish, and it will last until the bottle breaks. I never put iron solution into a graduate if I can avoid it, and by this plan I never need to do it.

"*Collodion.*—In regard to collodion, where only a small business is done, I have a plan not new but good, which I have practised almost constantly since 1865; it only needs to be tried to be adopted in every small gallery.

Ether, sulph. con.	20 ounces
Alcohol 95°	10 "
Cotton	200 grains

Put the cotton in the bottle and add the alcohol, shake well, so as to thoroughly wet the cotton, then add the ether. If the cotton is good it will leave no precipitate and will settle perfectly clear. It will keep indefinitely. This I call plain collodion.

Sensitizing Solution.

Alcohol	10 ounces
Iodide ammonium	200 grains
Bromide of cadmium	80 "

Or,

Alcohol	10 ounces
Iodide ammonium	150 grains
Iodide cadmium	60 "
Bromide cadmium	80 "

Dissolve the iodide and bromide in the alcohol by grinding in a glass mortar, and filter into a tall narrow bottle. This will keep indefinitely. When collodion is wanted, decant three ounces of plain collodion and add one ounce of the sensitizing solution. It will be fit for use immediately—but will be at its best in twenty-four hours. By this plan there is no old collodion standing by. Old red collodion may be renewed by setting a strip of clean scoured zinc into it; in a day or two a precipitate will be formed on the zinc, and the colour will be nearly or quite gone. This makes good ferrotype collodion, but is not so sensitive as new.

DISCOVERY OF OXYGEN IN THE SUN BY PHOTOGRAPHY, AND A NEW THEORY OF THE SOLAR SPECTRUM.

BY PROFESSOR DRAPER.*

I PROPOSE in this preliminary paper to indicate the means by which I have discovered oxygen, and probably nitrogen, in the sun, and also to present a new view of the constitution of the solar spectrum.

Oxygen discloses itself by bright lines or bands in the solar spectrum, and does not give dark absorption lines like the metals. We must therefore change our theory of the solar spectrum, and no longer regard it merely as a continuous spectrum with certain rays absorbed by a layer of ignited metallic vapours, but as having also bright lines and bands superposed on the background of continuous spectrum. Such a conception not only opens the way to the discovery of others of the non-metals, sulphur, phosphorus, selenium, chlorine, bromine, iodine, fluorine,

* Read before the American Philosophical Society, July 30th, 1877. This paper has been pronounced, by able judges, to be the most important contribution to solar physics since Kirchhoff's great discovery. It is just thirty-five years since the author's father, Dr. John W. Draper, read his first paper on Actinism, before the American Philosophical Society.—Ed. *Journal of Franklin Institute.*

carbon, &c., but also may account for some of the so-called dark lines, by regarding them as intervals between bright lines.

It must be distinctly understood that in speaking of the solar spectrum here, I do not mean the spectrum of any limited area upon the disc or margin of the sun, but the spectrum of light upon the whole disc. I have not used an image of the sun upon the slit of the spectroscopic, but have employed the beam reflected from the flat mirror of the heliostat without any condenser.

In support of the above assertions the accompanying photograph of the solar spectrum with a comparison spectrum of air, and also with some of the lines of iron and aluminium, is introduced. The photograph itself is absolutely free from handwork or retouching. It is difficult to bring out in a single photograph the best points of these various substances, and I have therefore selected from the collection of original negatives that one which shows the oxygen coincidences most plainly. There are so many variables among the conditions which conspire for the production of a spectrum, that many photographs must be taken to exhaust the best combinations. The pressure of the gas, the strength of the original current, the number of Leyden jars, the separation and nature of the terminal, the number of sparks per minute, and the duration of the interruption in each spark, are examples of the variables.

In the photograph the upper spectrum is that of the sun, and above it are the wave-lengths of some of the lines to serve as reference numbers. The wave-lengths used in this paper have been taken partly from Angstrom and partly from my photograph of the diffraction spectrum published in 1872. The lower spectrum is that of the open air Leyden spark, the terminals being one of iron and the other of aluminium. I have photographed oxygen, nitrogen, hydrogen, and carbonic acid, as well as other gases, in Plücker's tubes, and also in an apparatus in which the pressure could be varied, but for the present illustration the open air spark was, all things considered, best. By other arrangements the nitrogen lines can readily be made as sharp as the oxygen are here, and the iron lines may be increased in number and distinctness. For the metals the electric arc gives the best photographic results, as Lockyer has so well shown; but as my object was only to prove by the iron lines that the spectra had not shifted laterally past one another, those that are here shown at 4325, 4307, 4271, 4063, 4045 suffice. In the original collodion negative many more can be seen. Below the lower spectrum are the symbols for oxygen, nitrogen, iron, and aluminium.

No close observation is needed to demonstrate to even the most casual observer that the oxygen lines are found in the sun as bright lines, while the iron lines have dark representatives. The bright iron line at G (4307), on account of the intentional overlapping of the two spectra, can be seen passing up into the dark absorption line in the sun. At the same time the quadruple oxygen line between 4345 and 4350 coincides exactly with the bright group in the solar spectrum above. This oxygen group alone is almost sufficient to prove the presence of oxygen in the sun, for not only does each of the four components have a representative in the solar spectrum, but the relative strength and the general aspect of the lines in each case are similar. I do not think that in comparisons of the spectra of the elements and sun, enough stress has been laid on the general appearance of lines apart from their mere position; in photographic representations this point is very prominent. The fine double line at 4319, 4317 is plainly represented in the sun. Again there is a remarkable coincidence in the double line at 4190, 4184. The line at 4133 is very distinctly marked. The strongest oxygen line is the triple one at 4076, 4072, 4069, and here again a fine coincidence is seen, though the air spectrum seems proportionately stronger than the solar. But it must be remembered that the solar spectrum has

suffered from the transmission through our atmosphere and this effect is plainest in the absorption at the ultra-violet and violet regions of the spectrum. From some experiments I made in the summer of 1873 it appeared that this local absorption is so great when a maximum thickness of air intervenes, that the exposure necessary to obtain the ultra-violet spectrum at sunset was two hundred times as long as at midday. I was at that time seeking for atmospheric lines above H like those at the red end of the spectrum, but it turned out that the absorptive action at the more refrangible end is a progressive enfeebling as if a wedge of neutral tinted glass were being drawn lengthwise along the spectrum towards the less refrangible end.

I shall not attempt at this time to give a complete list of the oxygen lines with their wave lengths accurately determined, and it will be noticed that some lines in the air spectrum which have bright analogues in the sun are not marked with the symbol of oxygen. This is because there has not yet been an opportunity to make the necessary detailed comparisons. In order to be certain that a line belongs to oxygen, I have compared, under various pressures, the spectra of air, oxygen, nitrogen, carbonic acid, carburated hydrogen, hydrogen, and cyanogen. Where these gases were in Plücker's tubes a double series of photographs has been needed, one set taken with, and the other without, Leyden jars.

As to the spectrum of nitrogen and the existence of this element in the sun, there is not yet certainty. Nevertheless, even by comparing the diffused nitrogen lines of this particular photograph, in which nitrogen has been sacrificed to get the best effect for oxygen, the character of the evidence appears. The triple band between 4240, 4227, if traced upward into the sun has approximate representatives. Again at 4041 the same thing is seen, the solar bright line being especially marked. In another photograph the heavy line at 3995, which in this picture is opposite an insufficiently exposed part of the solar spectrum, shows a comparison band in the sun.

The reason I did not use air in an exhausted Plücker's tube for the production of a photograph to illustrate this paper, and thus get both oxygen and nitrogen lines well defined at the same time, was partly because a brighter light can be obtained with the open air spark, on account of the stronger current that can be used. This permits the slit to be more closed, and of course gives a sharper picture. Besides, the open air spark enabled me to employ an iron terminal, and thus avoid any error arising from accidental displacement of the reference spectrum. In Plücker's tubes with a Leyden spark the nitrogen lines are as plain as those of oxygen here. As far as I have seen, oxygen does not exhibit the change in the character of its lines that is so remarkable in hydrogen under the influence of pressure as shown by Frankland and Lockyer.

The bright lines of oxygen in the spectrum of the solar disc have not been hitherto perceived, probably from the fact that in eye observation bright lines on a less bright background do not make the impression on the mind that dark lines do. When attention is called to their presence they are readily enough seen, even without the aid of a reference spectrum. The photograph, however, brings them into a greater prominence. From purely theoretical considerations derived from terrestrial chemistry and the nebular hypothesis, the presence of oxygen in the sun might have been strongly suspected, for this element is currently stated to form eight-ninths of the water of the globe, one-third of the crust of the earth, and one-fifth of the air, and should therefore probably be a large constituent of every member of the solar system. On the other hand, the discovery of oxygen, and probably other non-metals, in the sun gives increased strength to the nebular hypothesis, because to many persons the absence of this important group has presented a considerable difficulty.

SOLAR CAMERA WORK IN ENGLAND.

A RECORD of the hours of sunshine in this country suggests some curious reflections as to the difficulty—or almost impossibility—of conducting solar camera work to advantage. The same record is discouraging to photographers generally, as suggesting how small the proportion of really fine light is afforded for photographic work. But for successful solar camera work absolute sunshine is required, and, as the record shows little over three hours a-day on an average, practical operations requiring it must be straightly limited.

The *Scientific American* calls attention to the report for the year ending April, 1877, in which there were, according to this register, only 1,200 hours of sunshine at Greenwich, or an average of a trifle over 3½ hours per diem. The monthly record was as follows:—

May	152.3
June	184.5
July	214.3
August	216.9
September	106.1
October	47.3
November	35.9
December	6.5
January	18.7
February	36.4
March	99.3
April	71.8

It says:—"We have not at hand any reliable register of sunshine in New York like the above; but it is within the experience of every one living here that our periods of sunshine far surpass those of London. For example, London makes the beggarly show of only six and-a-half hours of sun during the entire month of December. In New York we have in December many days of solar brilliancy, any one of which would register more hours of sunshine than the Londoners get during the whole month." The writer adds:—"We hope that some one will introduce the globe lens here, and ascertain the exact sunny records for this latitude. The instrument would form a useful addition to the meteorological observatory of the Central Park."

The self-registering sun-dial at the Royal Observatory at Greenwich, employed to indicate and record the daily duration of sunshine, consists of a lens made in the form of a ball, of glass, four inches in diameter, supported concentrically with a metallic bowl. The focus of the ball lens falls on the concave surface of the bowl, in which is placed a strip of suitable combustible material; the arrangement being such that, when the sun shines, the material is charred and a burned line is made, the length and position of which indicate the time and the duration of the solar radiance.

ROYAL CORNWALL POLYTECHNIC SOCIETY.

THE judges of the photographic department of the Royal Cornwall Polytechnic Society have just made their awards on a very excellent collection of pictures having been sent for competition. We shall publish a full report with names of the judges in our next. We may mention that Mr. Wm. Brooks was summoned from his residence in the neighbourhood of Red Hill to take part in making the awards. The following medals have been awarded:—

To Professional Photographers.

H. P. Robinson, first silver; F. Frith and Co., first silver; Geo. Nesbitt, first silver; J. Mullman Brown, first bronze; W. Gillard, first bronze; Reuben Mitchell, first silver; Wm. Harrison, special bronze.

To Amateur Photographers.

F. Beasley, first bronze; E. Brightman, first silver; H. Manfield, first bronze.

ADDING SCENIC BACKGROUNDS TO PORTRAIT NEGATIVES.

THE ingenious method of combining several negatives by superposing the films of various plates made or produced by many exposures, which was devised by Mr. A. Johnston, of Wick, some years ago, has been slow in coming into general application. Mr. Diston, of Fife (as we have been recently told by Dr. Nicol), has successfully used this method in producing *genre* studies by photography; and more recently we learn that it has been applied in America, the last issue of the *St. Louis Practical Photographer* having a very good illustration produced by the aid of this method. Mr. Johnston's method, it will be remembered, consisted in producing the first negative, of probably the principal figure or object with a black or transparent background. The films of subsequent negatives were then transferred to the first, any portion of the objects, in each superposed film, which might intrude where it was not required, being removed by a camel's-hair pencil and cyanide, or cyanide and iodine. Mr. Johnston gave full instructions in a little pamphlet which he issued. Since then he has described the method in our *YEAR-BOOK*. The results, when the manipulation is well managed, are exceedingly satisfactory.

In the *Practical Photographer* the illustration is entitled "Farewell." A pretty and graceful girl is waving adieu to friends from the deck of a boat, beside the bulwarks of which she stands, one hand resting on some ropes fastened round a belaying cleat. The sea, sky, and distant shore are put in by the method we have mentioned.

Mr. James Paris, of Ripon, Wisconsin, describes his operations in producing the illustration. He says:—

"In making the negatives for our picture, 'Farewell,' I used a dark woollen background, which left the background in the negative nearly clear glass; and, for the side of the boat, I used the back of one of our side slips, and lined it off with black crayon to imitate the siding, and nailed a narrow strip on the edge to hide the ragged edge of the cloth and give it a more finished look.

"In the first place, you want a good transparent positive to make the negative from. The one I used was made with some of Newton's emulsion; that I made June 18, 1876, with an exposure of about 40 or 50 seconds, and developed with his new developer, described in the *Bulletin* for February 1877, page 57. It came up as quick as a bath plate. I used no preservative—just flowed with emulsion and washed under the tap till smooth, and exposed. They come as near the tone of the Levy slides as any I have seen, and nearly as fine. It is a view on Green Lake, about six miles from here. It was then placed in a front made to fit a Victoria box, with a hole cut in it to fit the positive, then placed opposite the side light, with the ground glass to the light and the bellows nearly drawn out. Then a cone, holding a half-size Voigtlander tube, was put on an eight by ten box and the image focussed sharply the right size and in the

right place on the glass, which can easily be done by holding the figure negative on the image on the ground glass. That being done, take a fine plate of glass (free from scratches) the same size of your negative, and after being in diluted nitric acid for a while, wash well and clean with rottenstone and alcohol (some of the old hands will know how to do that, I think); then flow with your ordinary collodion, to which three or four grains of cotton have been added to the ounce. Do not omit, or you cannot transfer the film so well. Then sensitise, as usual, and expose long enough to get a fine negative. I exposed one minute with the smallest stop and a good light (you must cover the space between the two boxes with a cloth, so as to have all the light come through the positive); develop and fix in hypo, and wash well; do not let it dry; have ready a ten by twelve porcelain tray, about half full of a thirty-grain solution of citric acid. If you use a five by eight plate, that will be about the right size to use; place the wet negative in it, and in about five minutes the film will leave the glass; if it should stick on the edges, loosen it carefully with a camel's-hair brush. Now take the figure negative, and place it in the dish close to the other glass, and, using the brush to guide it, slide the film carefully on to the negative; then take it by the lower corners and raise it up gently, to get the air-bubbles out; and if you are careful to get it in the right place on the ground glass, it will fit the figure negative exactly; now wash well, holding the negative and film by the lower edge, and set up to dry. Have ready middling strong solution of cyanide, to which a few drops of tincture of iodine have been added, and try it on an old, dry, unvarnished negative with a camel's hair brush; and when you see it begins to eat the figure out, by working over, it is ready; if not, add a few drops more of the iodine. Now lay a piece of white paper on a stand in front of a window, and with a fine brush go all over the figure and those parts you want to take out; keep working, and you will see the image over the figure disappear; be careful and not go over the figure, or it will make a bad spot; wash well, and let it dry; do not let it stand too long, or it will peel off, bringing the figure with it (I lost one that way); varnish and retouch it where required, and it is ready for printing. This may seem a long and tedious operation, but I assure you it is not. I made, transferred, and, took off the part over the figure, and varnished the six negatives sent you in about four hours, including the one spoilt."

MEASUREMENT OF HEIGHT OF CLOUDS.

BY A. MALLOCK.*

If the clouds remained practically stationary for any time, and with their contours unaltered, there would be no difficulty in measuring their height, for if such were the case the observers might agree to measure the altitude and position of some prominent feature in a cloud at the ends of a measured base, which would of course give the necessary data; but in general the clouds not only move too fast for this to be done, but their contours, partly from the effect of perspective and partly from other alterations, change rapidly also, so that what perhaps was at one moment a well-marked feature, may in five minutes become unrecognisable.

The observations, then, by which the heights of clouds are to be measured must first of all be simultaneous, and they ought to be made on as many points as possible to obviate the unavoidable uncertainty as to the actual identity of the points observed at each station.

To secure these objects I had recourse to photography, and the way in which the photographs were taken and analyzed I will now describe. A pair of cameras, of one of which fig. 1 is a section, were placed one at each end of a measured base-line, and the lenses pointed to the zenith by means of the levelling screws A A.

* Read before the British Association.

The dark slide (B) fits as a drawer below, and consists of a shallow box, the lid being opened after it is placed in position by means of the milled head (C). Simultaneous

Fig. 1.

exposure of the sensitive plates is insured by uncovering the lens by an electric magnet apparatus (E), both cameras being in one circuit.

After a photograph is taken it is necessary to know the exact position which the plate occupied with reference to the lens; and as it would be impossible—or, at least, very inconvenient—to be obliged to have all the plates and fittings of the slide made with sufficient accuracy to attain this knowledge, I have made use of an easier, and, at the same time, a more efficient plan.

H is a horizontal axis, fixed in one side of the camera, movable from the outside by the milled head (K). On this axis, in the same plane, and terminated in sharp points, are two arms (L), which, in their ordinary position, lie back flat and upright against the side of the camera; but after the photograph has been taken, and before the dark slide has been touched, the head (K) is turned so that points descend on the plate, and puncture the film in two places. As the axis (H) is fixed in the camera, and, therefore, fixed as regards the lens, the two punctures left on the film leave a trustworthy record of the position of the plate at the time of exposure.

The constants, which must be known for each camera before the photographs can be analysed, are:—

1. f , the distance of the optical centre of the lens from the plate.
2. The co-ordinates, x' and y' , of that point in the plate which corresponds to the zenith, the axis of x passing through to the points marked on the film, one of them being the origin.

To obtain these co-ordinates I photograph a target (fig. 2) placed in the zenith at such a distance from the camera

Fig. 2.

Fig. 3.

that a well defined picture may be taken without altering the adjustment of the lens. A plumb-line passes through the centre of the target, and the camera is placed in position by its means. x' and y' (fig. 3) are then the co-ordinates of the centre of the target in the photograph. I may here remark that any small difference between the optical and geometrical centre of the lens, such as is often found to exist, will produce errors of the second order only in the result. A comparison of the actual size of the target with that of the photograph will, of course, give f , but for

April	71.8

It says:—"We have not at hand any reliable register of sunshine in New York like the above; but it is within the experience of every one living here that our periods of sunshine far surpass those of London. For example, London makes the beggarly show of only six and-a-half hours of sun during the entire month of December. In New York we have in December many days of solar brilliancy, any one of which would register more hours of sunshine than the Londoners get during the whole month." The writer adds:—"We hope that some one will introduce the globe lens here, and ascertain the exact sunny records for this latitude. The instrument would form a useful addition to the meteorological observatory of the Central Park."

The self-registering sun-dial at the Royal Observatory at Greenwich, employed to indicate and record the daily duration of sunshine, consists of a lens made in the form of a ball, of glass, four inches in diameter, supported concentrically with a metallic bowl. The focus of the ball lens falls on the concave surface of the bowl, in which is placed a strip of suitable combustible material; the arrangement being such that, when the sun shines, the material is charred and a burned line is made, the length and position of which indicate the time and the duration of the solar radiance.

ROYAL CORNWALL POLYTECHNIC SOCIETY.

The judges of the photographic department of the Royal Cornwall Polytechnic Society have just made their awards, a very excellent collection of pictures having been sent for competition. We shall publish a full report with names of the judges in our next. We may mention that Mr. Wm. Brooks was summoned from his residence in the neighbourhood of Red Hill to take part in making the awards. The following medals have been awarded:—

To Professional Photographers.

H. P. Robinson, first silver; F. Frith and Co., first silver; Geo. Nesbitt, first silver; J. Mullman Brown, first bronze; W. Gillard, first bronze; Reuben Mitchell, first silver; Wm. Harrison, special bronze.

To Amateur Photographers.

F. Beasley, first bronze; E. Brightman, first silver; H. Manfield, first bronze.

ADDING SCENIC BACKGROUNDS TO PORTRAIT NEGATIVES.

THE ingenious method of combining several negatives by superposing the films of various plates made or produced by many exposures, which was devised by Mr. A. Johnston, of Wick, some years ago, has been slow in coming into general application. Mr. Diston, of Fife (as we have been recently told by Dr. Nicol), has successfully used this method in producing genre studies by photography; and more recently we learn that it has been applied in America, the last issue of the *St. Louis Practical Photographer* having a very good illustration produced by the aid of this method. Mr. Johnston's method, it will be remembered, consisted in producing the first negative, of probably the principal figure or object, with a black or transparent background. The films of subsequent negatives were then transferred to the first, any portion of the objects, in each superposed film, which might intrude where it was not required, being removed by a camel's-hair pencil and cyanide, or cyanide and iodine. Mr. Johnston gave full instructions in a little pamphlet which he issued. Since then he has described the method in our *Year-Book*. The results, when the manipulation is well managed, are exceedingly satisfactory.

In the *Practical Photographer* the illustration is entitled "Farewell." A pretty and graceful girl is waving adieu to friends from the deck of a boat, beside the bulwarks of which she stands, one hand resting on some ropes fastened round a belaying cleat. The sea, sky, and distant shore are put in by the method we have mentioned.

Mr. James Paris, of Ripon, Wisconsin, describes his operations in producing the illustration. He says:—

"In making the negatives for our picture, 'Farewell,' I used a dark woollen background, which left the background in the negative nearly clear glass; and, for the side of the boat, I used the back of one of our side slips, and lined it off with black crayon to imitate the siding, and nailed a narrow strip on the edge to hide the ragged edge of the cloth and give it a more finished look.

"In the first place, you want a good transparent positive to make the negative from. The one I used was made with some of Newton's emulsion; that I made June 18, 1876, with an exposure of about 40 or 50 seconds, and developed with his new developer, described in the *Bulletin* for February, 1877, page 57. It came up as quick as a bath plate. I used no preservative—just flowed with emulsion and washed under the tap till smooth, and exposed. They come as near the tone of the Levy slides as any I have seen, and nearly as fine. It is a view on Green Lake, about six miles from here. It was then placed in a front made to fit a Victoria box, with a hole cut in it to fit the positive, then placed opposite the side light, with the ground glass to the light, and the bellows nearly drawn out. Then a cone, holding a half-size Voigtlander tube, was put on an eight by ten box, and the image focussed sharply the right size and in the

right place on the glass, which can easily be done by holding the figure negative on the image on the ground glass. That being done, take a fine plate of glass (free from scratches) the same size of your negative, and after being in diluted nitric acid for a while, wash well and clean with rottenstone and alcohol (some of the old hands will know how to do that, I think); then flow with your ordinary collodion, to which three or four grains of cotton have been added to the ounce. Do not omit, or you cannot transfer the film so well. Then sensitise, as usual, and expose long enough to get a fine negative. I exposed one minute with the smallest stop and a good light (you must cover the space between the two boxes with a cloth, so as to have all the light come through the positive); develop and fix in hypo, and wash well; do not let it dry; have ready a ten by twelve porcelain tray, about half full of a thirty-grain solution of citric acid. If you use a five by eight plate, that will be about the right size to use; place the wet negative in it, and in about five minutes the film will leave the glass; if it should stick on the edges, loosen it carefully with a camel's-hair brush. Now take the figure negative, and place it in the dish close to the other glass, and, using the brush to guide it, slide the film carefully on to the negative; then take it by the lower corners and raise it up gently, to get the air-bubbles out; and if you are careful to get it in the right place on the ground glass, it will fit the figure negative exactly; now wash well, holding the negative and film by the lower edge, and set up to dry. Have ready middling strong solution of cyanide, to which a few drops of tincture of iodine have been added, and try it on an old, dry, unvarnished negative with a camel's hair brush; and when you see it begins to eat the figure out, by working over, it is ready; if not, add a few drops more of the iodine. Now lay a piece of white paper on a stand in front of a window, and with a fine brush go all over the figure and those parts you want to take out; keep working, and you will see the image over the figure disappear; be careful and not go over the figure, or it will make a bad spot; wash well, and let it dry; do not let it stand too long, or it will peel off, bringing the figure with it (I lost one that way); varnish and retouch it where required, and it is ready for printing. This may seem a long and tedious operation, but I assure you it is not. I made, transferred, and took off the part over the figure, and varnished the six negatives sent you in about four hours, including the one spoil."

MEASUREMENT OF HEIGHT OF CLOUDS.

BY A. MALLOCK.*

If the clouds remained practically stationary for any time, and with their contours unaltered, there would be no difficulty in measuring their height, for if such were the case the observers might agree to measure the altitude and position of some prominent feature in a cloud at the ends of a measured base, which would of course give the necessary data; but in general the clouds not only move too fast for this to be done, but their contours, partly from the effect of perspective and partly from other alterations, change rapidly also, so that what perhaps was at one moment a well-marked feature, may in five minutes become unrecognisable.

The observations, then, by which the heights of clouds are to be measured must first of all be simultaneous, and they ought to be made on as many points as possible to obviate the unavoidable uncertainty as to the actual identity of the points observed at each station.

To secure these objects I had recourse to photography, and the way in which the photographs were taken and analyzed I will now describe. A pair of cameras, of one of which fig. 1 is a section, were placed one at each end of a measured base-line, and the lenses pointed to the zenith by means of the levelling screws A A.

* Read before the British Association.

The dark slide (B) fits as a drawer below, and consists of a shallow box, the lid being opened after it is placed in position by means of the milled head (C). Simultaneous

Fig. 1.

exposure of the sensitive plates is insured by uncovering the lens by an electric magnet apparatus (E), both cameras being in one circuit.

After a photograph is taken it is necessary to know the exact position which the plate occupied with reference to the lens; and as it would be impossible—or, at least, very inconvenient—to be obliged to have all the plates and fittings of the slide made with sufficient accuracy to attain this knowledge, I have made use of an easier, and, at the same time, a more efficient plan.

H is a horizontal axis, fixed in one side of the camera, movable from the outside by the milled head (K). On this axis, in the same plane, and terminated in sharp points, are two arms (L), which, in their ordinary position, lie back flat and upright against the side of the camera; but after the photograph has been taken, and before the dark slide has been touched, the head (K) is turned so that points descend on the plate, and puncture the film in two places. As the axis (H) is fixed in the camera, and, therefore, fixed as regards the lens, the two punctures left on the film leave a trustworthy record of the position of the plate at the time of exposure.

The constants, which must be known for each camera before the photographs can be analysed, are:—

1. f , the distance of the optical centre of the lens from the plate.
2. The co-ordinates, x' and y' , of that point in the plate which corresponds to the zenith, the axis of x passing through to the points marked on the film, one of them being the origin.

To obtain these co-ordinates I photograph a target (fig. 2) placed in the zenith at such a distance from the camera

Fig. 2.

Fig. 3.

that a well defined picture may be taken without altering the adjustment of the lens. A plumb-line passes through the centre of the target, and the camera is placed in position by its means. x' and y' (fig. 3) are then the co-ordinates of the centre of the target in the photograph. I may here remark that any small difference between the optical and geometrical centre of the lens, such as is often found to exist, will produce errors of the second order only in the result. A comparison of the actual size of the target with that of the photograph will, of course, give f , but for

greater certainty I measured f also by taking another photograph with the camera displaced horizontally by a known amount from its first position immediately under the target.

Having got these constants, the analysis of any pair of photographs is very easy. What has to be found is the tangent of the parallax which the cloud would have if it were immediately over one of the cameras, which may be expressed in this case as the difference of the projections on the line joining the two cameras of the distance of corresponding points in the photographs. [The author then described the trigonometrical method of calculating the parallax, and finally showed that $h = p \cdot L$, whence $h =$ height of the cloud, $L =$ length of the base, $p = \frac{d}{f}$, d being the difference of the measured points in the photographic paper, and f the focal length of the lens.]

It will be noticed that it is not the distance of the cloud from the camera, but its perpendicular distance from the earth, and this due to the fact of the plate being horizontal, that is concentric with the surface of the earth. What is really measured is the distance of the cloud from the plane of the plate, so that had any other direction than the vertical been given to the camera—which, of course, might be done—another factor, the same nearly of the angle of elevation of the camera, would appear in the result. There are several advantages, however, in placing the cameras vertically, among which may be mentioned that it is always easy, by means of levels, to ensure a known line in each instrument being vertical; whereas to ensure parallelism in the direction of the cameras in any other case requires an adjustment in azimuth, which becomes more and more important as the direction chosen deviates further from the vertical. The disadvantage of placing the cameras vertical is, that very often the clouds which it may be required to photograph do not show in the **field**.

With regard to the practical part of the analysis, I find that the quickest and most convenient way of finding d is to place the negatives side by side in a frame fitted with a reflector, and with a fine needle to mark a number of corresponding points in each picture; the co-ordinates of these points are then measured by a micrometer, and the points so found, together with the zenith points, are plotted to an enlarged scale, one set of measures being plotted on tracing paper. The tracing is then applied to the other drawing, so that the corresponding points in each may fit as well as possible. The distance between the zenith point in the tracing and drawing $= d$, and the line through them is the direction of the line joining the two cameras. I find it quicker to arrive at the direction of the base-line by drawing than by calculation, while at the same time the drawings give greater facility for distributing the errors advantageously. As to the length of the base-line to be employed, I should say that the shorter it is in reason the better. That which I used was about two hundred yards. Undoubtedly the shorter it is the more convenient, and also, as clouds are often very thick, their contours may, if the base be long, be so different, according as to whether they are seen from one end or the other, as to make the photograph practically useless.

The results obtained are, I have reason to believe, accurate within five per cent., which is quite near enough for all practical purposes. This refers principally to measures of high clouds. Rain clouds were found as high as 4,000 feet. Cumulus was seldom lower than 6,000 or more than 8,000 feet; cirro-cumulus up to 20,000, and cirrus to 28,000 and 30,000 feet. Isolated measures like these cannot, of course, lead to much; but if this method was used systematically at observatories, much interesting information might, no doubt, be obtained about the formation of cirrus clouds, and also about the winds in the higher strata of the atmosphere.

SILVER MUD.

In Wasco county, Oregon, there is a flat, thickly studded with springs of a peculiar character, that throw out mud which has overflowed a considerable area. Some months ago it was reported that this mud had been discovered to be argentiferous and very rich, some specimens amounting over \$2,000 to the ton. An effort was made to organize a company in this city to work the mud springs, but the enterprise collapsed in consequence of a suspicion raised that the mud had been "salted," and the memorable Arizona diamond field swindle was too fresh in recollection for the successful prosecution of another fraud in the same line. Professor Thomas Price analyzed samples submitted, and reported that he had discovered unmistakable evidence of "salting," the microscope showing filings, crystals, and free gold, which he had no hesitation in declaring had been mixed in with the mud with the manifest design of instituting a great swindle. Professor H. G. Hanks also examined specimens, but while he was inclined to suspect fraud, he was unable to determine positively whether the argentiferous mud was an artificial or natural production. Professor Hanks now intimates that the flow of the Oregon mud springs is in reality heavily impregnated with silver, and this result he announced in a paper read before the California State Geological Society. The existence of springs yielding soft mud charged with free silver, says Professor Hanks, is new to science, and scientific men, both here and at the East, who examined specimens, pronounced them fictitious without hesitation. The specimens latterly examined by Professor Hanks, he says, were very rich, and silver was discovered in a free state. By simple washing the silver could be wholly separated, and when then examined the microscope failed to reveal the source of the precious metal. Had it been filings, a single glance would have sufficed to detect the fact. Had the silver been precipitated from solution by copper it would have been crystallized. An amalgam of silver and mercury would have yielded a sublimate if strongly heated in a glass tube closed at one end. Such an amalgam introduced into the wet mud, and the whole heated sufficiently to have volatilized the mercury, would have left the substance in a hard baked state, which could not again have been reduced to the state in which it reached this city.

From these conclusions, if the silver had been introduced for fraudulent purposes, the substance was very remarkable, from the fact that some process had been employed not easily understood. Professor Hanks finally obtained the address of a gentleman, Richard Hurley, residing in the vicinity of the wonderful springs in Wasco county, and applied to him for information. In reply to Professor Hanks, Mr. Hurley writes: "There is no mistake as to this mud containing silver. I have assayed over 100 samples which contained silver, some as high as \$2,300 to the ton. The samples I obtained from the spring myself. I think the weather has considerably to do with the mud containing silver. I obtain the best results when the weather is warm. Sometimes in one of the larger springs, when the weather is cold, the mud will be of a yellow colour, showing no silver; but when the day is warm, the mud is blackish-blue, at least in places, and rich in silver. The springs seem to work more actively in a warm afternoon. Some of them contain a great deal of acid, the bones of animals that fall into them being dissolved in a few months. There are old wells which assay from \$5 to \$1,200 to the ton. One assay I made from the flat, half a mile from any spring, assayed \$1,200 to the ton. There is a great deal of salt, almost pure, all over the spring flat. There are between 100 and 200 quartz leads discovered, running in two directions close to the spring. I find silver in several of them, all the way from a few dollars to \$100 to the ton. Some of these leads run through the springs, at least they point in that direction. The altitude of this place is between 4,000 and 5,000 feet."

Professor Hanks also refers in his paper to the recent dis-

covery of a peculiar silver-bearing deposit located in South-western Utah. It occurs in the "Maud Mine," six miles from Leeds. Some assays as high as \$700 per ton have been made. Instead of being sandstone, as supposed, Professor Hanks found this deposit to be sedimentary, but closely resembling the Oregon mud. Under the microscope it has all the appearance of that strange substance. The Oregon mud, if allowed to dry in large quantities, would soon form a similar substance to the Utah mineral, in appearance at least. The silver is in the state of chloride, and is seen under the microscope both amorphous and in crystals. An analysis of the two minerals will be interesting, and may throw some new light on the subject. It is possible that a study of these deposits may contribute much to our knowledge of the formation of metalliferous veins.—*San Francisco Examiner*.

ARTISTIC PRINCIPLES AND MECHANICAL OPERATIONS IN PORTRAITURE.

BY G. W. HITE.*

HAVING been frequently called upon to express an opinion relative to the theory of combining artistic principles with the mechanical operation of taking likenesses by the photographic process, I will give you that which I have gleaned from what I think the best authority, together with my own experience.

The room in which the sittings are taken should have but one light, looking northward, because the light continues the same, and is not subject to the changes caused by the passage of the sun in rooms receiving the light from other quarters. An east light is nearly as good, if the room has a window; but if a sky-light, it is influenced by the oblique rays of the sun, till it has passed the meridian. The light should be so high as to fall upon the person sitting; the distance they should be placed, and the consequent angle of light, must be determined by taste, and governed by the capacity or field of the camera, and the character of the party sitting. If a window, the light should be excluded from the lower part, near which the camera stands, to give the fullest and most perfect form to the shadows of the face, which might otherwise be cut up by under-reflections.

Fine developments of the forehead should be placed so that all the ocular forms can be distinctly delineated, in combination with the cast or deep shadows under the brows, which, though richly and strongly marked, must be transparent in the picture, to produce an effect which the reflected light from the upper part of the cheek and surrounding points always introduces. Studying a favorable position for the eyes, and producing a picturesque appearance in the brows, the shadows from the nose and under lip are almost sure to accord.

Delicate features—women and children—require a treatment as delicate; and great attention should be paid to so place them as to preserve it. Enough shadow must, however, be introduced to preserve the roundness, and render expressive every sweet and tender undulation.

The person should sit about three yards from the camera (nearer approach is generally discovered in the picture), the features drooping, &c. The camera standing higher than the subject introduces the same faults, unless the angular position in which the person sits requires an elevation of the camera—so that the lens would be on a parallel line with the sitter. It is well to sit the person so that the face is a little higher than the camera, and place an object at such distance as the eye of the sitter can fairly reach without much motion. In the eyes, great variety presents itself; and it is particularly necessary to observe the iris of the eye—the whole circle being seen in full eyes. In eyes less full the iris passes up under the upper lids, &c. The person should never be set so much sideways as to bring the eyes strained into the corners.

* *Practical Photographer.*

Notwithstanding the stationary character of the nose, it demands great consideration in adjusting the sitter. From various causes the cartilage of the nose is seldom uniform or perpendicular on the face. It must be inspected full-faced, right-and-left, three-quarter, and in profile, to gather from the variations the form which suits with the presiding expression in the combined features. An irregular aquiline nose inspected in a three-quarter view will appear hooked with the one cheek toward you, and inverted on the other, arising from the insertion of the cartilage to the nasal bone projecting unequally on one side, and proceeding in an angular direction towards the tip of the nose. An inequality of size or form in the nostrils will also have an influence on the character of the picture. Hence it is expedient for those who are unacquainted with these causes and effects to examine extreme cases, which, being very apparent, will give a judgment, where the case is only perceptible to the practitioner from its slight deviation from regularity.

So great is the difference in many faces, when inspected in opposite directions, that one of the two views, however accurately taken, would not communicate the likeness—it not being the usually observed characteristic form. When the right view of the head is obtained, it is first necessary to consider the size of the plate it is to be taken on, so as to form an idea of the proportion the head should bear to it. The mind must arrange these points before we commence, or we shall find everything too large or too small for the happy proportion of the picture and the conveying of a just notion of the stature. The work will have to be done over, and time sacrificed, if this is not attended to. The adjustment of the head to the size of the plate (as seen from the margin of the mat) is not to be taught: every one must bring himself, by scrutinizing practice, to mathematical accuracy; for something will be discovered in every face which can be surmounted only by experience.

The eye nearest the camera, in a three-quarter face, is placed in the middle of the breadth of the plate; the chin, in a person of middle stature, in the middle of the length; and higher according to the proportional height of the person.

From tranquility to the smile may be ranked as familiar expressions, unexceptionable for portraits, and not subject to capricious observation. But as there is such a variety of temperaments, we will seldom find persons who can control this most desirable point for a photograph. Much, however, depends upon the associations that are brought about upon the spur of the moment.

In conclusion, I would say to operators generally, that rigid practice renders accuracy habitual, and a pleasure; slovenly operations generate labor and difficulties.

A NEW THEORY OF THE SOLAR SPECTRUM.*

At a time when the nebular hypothesis has formed the groundwork of several papers read at the just concluded meeting of the British Association, news has arrived from America of what promises to be one of the greatest discoveries in solar physics since those of Kirchhoff—a discovery, moreover, which supports the nebular hypothesis by removing one of the difficulties which stood in the way of its general acceptance. If the light of the sun as it passes through a narrow slit is examined by means of a prism a number of dark lines will be seen crossing the spectrum parallel to the line of the slit. Some of these lines are better defined than others, and at a first glance they are seen to be more numerous in some parts of the spectrum than in others. These lines were first discovered by Wollaston, the celebrated English chemist, but they are known as Fraunhofer's lines because they were first accurately mapped by the German optician. Fraunhofer also established the fact that the lines are not due to any interference of our atmosphere, by showing that the lines, when seen in the spectra of

* *The Echo*

the moon and planets, are arranged in exactly the same way as they are in the spectrum of the sun which is the source of light for those reflectors, while the spectra of the fixed stars exhibit not only different groups of lines, but different arrangements. If we examine the spectrum of a gas-flame we find it to be what is termed continuous—that is, it does not exhibit any dark lines, which are in reality due to the absence of rays of the refrangibility due to that part of the spectrum; the light of the gas is simply due to the incandescence of the solid particles of carbon, and with all incandescent substances we have a spectrum unmarked by dark lines. But with bodies in the state of gas or vapour we obtain discontinuous spectra, which are characterised by more or less prominent distinguishing features. Thus, if we volatilise a salt of sodium, such as common salt, and examine the luminous metallic vapour by means of the spectroscope, we find a bright yellow line as the characteristic indication of the presence of the metal sodium, and we find also that this line corresponds to the dark line which is marked as D on the charts of the solar spectrum.

Other metals give peculiar or special bright bands in their spectra, which correspond to dark lines in the solar spectrum, and the question naturally arises, why are the bands dark in the spectrum of the sun if they correspond to the bright bands of the spectra of metallic vapours? This question was answered by Kirchhoff, who propounded a new theory of the sun's constitution. Kirchhoff found that the vapour of burning sodium has the power of absorbing rays of the same refrangibility as those which it emits, and the same is true of other metals. Hence, after making a numerous series of experiments, he concluded that the mass of the sun is an intensely white-hot surface, emitting white light; but it is surrounded by an envelope of vapours of the burning metals, which absorb the rays issuing from the white-hot mass within, just as the vapour of sodium in the lecture-room absorbs those rays of an artificial light which are of the same refrangibility as those which it emits. From Kirchhoff's discovery, then, we know, as well as we can know anything, that the sun contains sodium, calcium, strontium, iron, hydrogen, &c.; but we did not know, until the remarkable discovery recently announced by Professor Henry Draper, M.D., in the United States, that the spectrum of the sun betrayed the presence of oxygen, and probably also of nitrogen. His discovery—corroborated by a photograph of the solar spectrum side by side with that of atmospheric air—shows that oxygen discloses itself by bright lines in the solar spectrum, and does not give dark lines like the metals. The theory of the solar spectrum must, therefore, be corrected; for we can no longer regard it merely as a continuous spectrum, with certain rays absorbed by metallic vapours, but as having bright lines superposed on the background of the continuous spectrum. Professor Draper's discovery, which has yet to be worked out, is of especial importance, for it shows that the non-metals may behave differently to the metals, and that, consequently, there may be many more elements in the sun than has hitherto been supposed; and, as mentioned above, it is one more fact in favour of the nebular hypothesis. On purely theoretical considerations, derived from terrestrial chemistry and the nebular hypothesis, it would seem that oxygen must be present in the sun, besides other non-metals; and this discovery will give renewed impetus to the investigations of spectroscopists. It may appear to those unacquainted with the spectroscope that the practical utility of these discoveries is very small; but, apart from the fact that all knowledge must be useful, the spectroscope is a very valuable instrument in the hands of the analyst, for it enables him to detect the presence of metals in the minutest quantities. To give only one instance of its practical utility, if it were desired to test whether a well is polluted by the leakage of a drain, it would suffice to pour into the latter a quantity of lithia solution—for the metal lithium can be infallibly detected by spectrum analysis—and its presence in the well-water would be positive proof of communication between the drain and the well.

PRICES OF PORTRAITURE IN AMERICA.

Mr. J. CADWALLADER, an Indianapolis photographer, discourses in some of our American contemporaries on the subject of prices. He asks, "Shall prices come down?" and adds:—

"This question is forced upon us by the stringency of the times. For one, I favour holding up prices. If other localities can maintain good prices, I think we can do the same here. The leading galleries throughout the country should set the example, and we of smaller pretensions should try to follow.

"Now let every artist in the country give his views on this vital subject. What are the prices which should prevail? And what prices do you obtain?

"A full expression from the fraternity may give courage and confidence to many. It may enable many of us to adopt a better course to pursue in the future—to know just how the business is managed, and what prices prevail in other sections of the country. Is it expedient, in the present depressed condition of the country, to lower prices? I think not. What say you, gentlemen of the camera? I wish that a thousand artists from every part of the country would give their prices, that we may each see what others are accomplishing. Then, if any of us see that better prices prevail, and the business of the galleries which obtain the better prices is prospered thereby, it may strengthen such as are weak, and stimulate them to obtain better prices.

"In the multitude of counsel there is strength. If, in the judgment of the united fraternity, the exigencies of the times require a reduction in prices, then let us be governed accordingly, and drop on the prices all along the line. But, as before stated, I for one do not think it expedient to lower prices.

"This city has a population of 100,000, and about twenty-five galleries, some of which are very good. L. D. Jenkins is a good photographer and has a good gallery, and gets \$5 for cards, but I regret to say that at another gallery in the city, owned by him, he hangs out a \$2 sign. I believe that no man in the business knows better than does L. D. J. that \$2 is not the best thing.

"Smith and Dryer have recently opened a very nice gallery, all on the second floor, and are getting \$5 for cards, and say they will maintain good prices. Mr. Smith is a new man in the business. Mr. Dryer has been well known as an artist for years, having been one of the Government artists at the transit of Venus.

"D. R. Clark has one of the best galleries in the city; is making cards at \$4, cabinets at \$8. Harry Fowler, well known in this city for years, holds firm at \$5 for cards. J. H. Dunn has just reopened in a new building; \$3 for cards. W. H. Potter has a good gallery; he reduced last winter to 4 for cards. Then there are other galleries; each seems to be vying with the other to get at bottom figures for cards.

"Now if my views in this matter meet those of the fraternity generally, and the Editor, after a few months of interchange of ideas a great amount of good may be done.

"My individual theory is that, amongst galleries which do good work and are kept clean, there should be a uniformity in prices. At least there should be a recognized and established price, below which no artist should feel himself at liberty to go. It is plain that if such were the established rules of the craft, it would be a great benefit to the whole. With a little broader application of this proposition it becomes equally plain that any system which benefits the whole is likewise a benefit to the individuals who compose the whole.

"Therefore, as the beginning of the tally which I have suggested, I offer the following schedule of prices, which now prevail in my gallery, and which have been established during five years:—

Cards, half-dozen	\$3 50
" 1 "	5 00
" duplicate, per dozen...	3 00

Cabinet, 1	3 00
" half-dozen	6 00
" 1	10 00
" duplicate, per dozen	8 00
4 by 4, 1	4 00
4 by 4, duplicate	1 50
8 by 10, 1	6 00
8 by 10 duplicate	2 00
11 by 14, 1	10 00
11 by 14, duplicate	5 00
14 by 17, 1	15 00
14 by 17, duplicate	8 00

Correspondence.

M. ROUSSELON'S CLAIM TO AN ENGRAVING PROCESS.

SIR,—In your issue of August 10th, and under the head of "M. Rousselon's Photo-gravure process," I see that that gentleman has now come forward before the Photographic Society of France as claimant to being the first discoverer of reliefs possessing grain by which photo-engraved plates could be obtained, and that a publication of M. Placet's has been the immediate cause of his bringing forward this, as you justly style it, extraordinary claim. Now, as you are aware, for some years past I have repeatedly challenged M. Rousselon, through the medium of this and other journals, to show in what the manner employed by him differed from the one discovered and put in practice by me in his atelier at Asnières, in the year 1869, and which method I communicated to him at the same time. The articles I allude to were translated into French and other journals, and yet they were never replied to. He says, in his letter to the French Society, "My discovery has already brought me awards from Vienna, Brussels, London, and Paris." But it could not have been a discovery that obtained him these, but certain results obtained in a particular manner. I should hardly think that in France (as I am sure they would not in England) that award would be given for a discovery, unless the recipient of such award proved that he had discovered something, which M. Rousselon has never yet done, and which I now again challenge him to do, and also that he was not materially assisted by me in an improvement of great importance to the success of the process.

I may add that M. Placet's methods of obtaining grain for engraved plates are based on an entirely different principle to mine, though a method lately put forward as invented by M. Despaquis is almost identical with the latter.

WALTER B. WOODBURY.

Dusseldorf, August 10th.

REMOVING NITRATE SALTS FROM GELATINE EMULSION.

SIR,—We observe, in your issue of the 24th August, a letter from Mr. Herbert Kerr, claiming for Colonel Wortley the discovery made and published by Mr. Wratten in your paper of the 17th August. Your appendix to the said article is good; yet, as he seems to have been incapable of perusing the said article with profit to himself, we solicit permission to tell him the gist of the matter, and thus set his mind at ease. We do not, then, pour out the emulsion to "set," nor wash it with water, nor soak it in alcohol for the mere final purpose of extracting the water, as did Colonel Wortley. We add the alcohol direct to the emulsion for the specific purpose of extracting the nitrate salt formed by double decomposition, well knowing that if we extract the water holding it in solution its extraction is a necessary accompaniment. This the grand and all-important point Colonel Wortley seems to fail to comprehend. Need we ask why?—Respectfully yours,

WRATTEN AND WAINWRIGHT.

38, Great Queen Street, Long Acre, W.C.

PHOTOGRAPHY AT THE SEAT OF WAR.

SIR,—I notice Dr. Vogel says in last week's article that it is a difficult matter to get permission to take photographs at the seat of war, either from Russian or Turkish side. I have a special permission from the Turkish Government to photograph in Asia, and since I have returned to England I have an invitation from one of the Pashas to join his staff to take photographs. The only difficulty I ever experienced in going anywhere, or doing anything, was the want of money. I should have done more, and gone further, if this had been supplied to me. I would undertake to reach Chipka Pass in fourteen days after starting from London, and also secure photographs, if the sinews of war were forthcoming.—I am,

ED. POCCOCK.

Proceedings of Societies.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE monthly summer meeting of this Association was held on Saturday, the 25th instant. At the invitation of the President the members met at his residence, Clare Mount, Wallasey. Unfortunately the weather turned out in every way unfavourable for photography, and, though a walk was taken to the old tower, it was considered useless to expose a single plate. On returning to Clare Mount two attempts were made to obtain on a wet plate a group of the members; but, although exposures of a minute and a-half and three minutes were given, only a faint positive was the result.

The rain coming down heavily, an adjournment was made indoors, where the members proceeded to do justice to the President's hospitality by demonstrating that, however skilled they were in preparing emulsions, they were no less adepts at the tea and coffee process, and were capital hands at cleaning plates.

The President showed a number of negatives and prints taken during his tour in Switzerland and Yorkshire, and afterwards took the members into his dark room, where he gave a demonstration of the manner of preparing gelatine emulsion by Mr. Wratten's method. He coated a number of plates, brought by the members, with gelatine emulsion, and finally took an enlargement by Leach's process, with the aid of the sciopicon.

Mr. W. E. POTTER demonstrated the manner in which he packed his whole-plate camera and double backs on his bicycle, and stated that he found no inconvenience in travelling thus laden. He exhibited a print of a pretty view near Llangollen which had been taken on one of his trips.

Mr. J. H. T. ELLIOTT showed a number of fine prints taken in Wales.

Mr. J. A. FORRESTER exhibited a number of beautiful views, chiefly of the interior of the Town Hall, Manchester, taken by Mr. J. Pollitt on wet collodion plates. Although the exposures varied from two minutes to six hours, all were charmingly soft and full of detail, without any of the blurring so often seen about the windows of interiors. They were doubly interesting to photographers, as each print was marked with the name of the lens by which it was taken, size of stop, and length of exposure.

Mr. W. ROPER, of Lancaster, was elected a member of the Association.

The usual monthly evening meetings will be resumed at the Free Library on the last Thursday in September.

Talk in the Studio.

PHYSIOLOGICAL PHOTOGRAPHS.—At the recent meeting of the British Association, under the title of "Photographs of Representations of Vascular Injections, by Professor Dantscher, of Innsbruck," an abstract of a paper by Professor Allen Thomson was read by one of the secretaries. In this paper Professor Thomson brought under the notice of the section the approaching publication of a series of photographic representations of the "minute distribution of bloodvessels in a number of the organs of the animal body made under the superintendence of Professor Dantscher, of the university of Innsbruck, from injected and corroded preparations made by himself. Dr. Thomson saw some of these preparations some years ago at Innsbruck, and admired them much. The collection had since been much increased, and the photographs executed

partly on paper and partly on glasses, and some of them coloured after the original preparations are capable of being viewed with the stereoscope so as to give a truthful and instructive view of the beautiful structures they represent. Dr. Thomson regretted that accidental circumstances made it impossible for him to show some of the photographs to the section, but it was stated that they would be presented to the meeting of German naturalists at Munich in September.—No discussion took place.

THE RECENT ECLIPSE.—The Rev. C. Fritchard, writing to the *Times* of the late eclipse of the moon, says:—"Before and during the progress of the eclipse many photographs were taken by Mr. Jenkins, with Dr. De La Rue's 13in. reflector, and when these are critically scrutinized it is hoped that some light may be thrown on the extent of the earth's atmosphere, because it may be assumed that, owing to the absorption of actinic rays by our atmosphere, the photographic shadow may extend and be traceable a long way beyond the true penumbra. The exposure of a photographic plate to the telescopic image of the totally eclipsed moon for two minutes produced no effects as yet discernible."

AMERICAN COMPETITION IN MECHANICAL PRINTING.—The *Scientific American* describes the curious competition in the States between two rival photo-mechanical printing establishments. It says:—"A short time since the (U.S.) Treasury advertised for bids for printing bank checks at so much per thousand, and there was so much rivalry between the American Phototype Company and the Graphic Company that each of them determined to get it if possible. The Phototype Company bid for the job at $\frac{1}{4}$ of a mill per thousand, and the Graphic, not to be beaten, offered to do it for nothing, and the contract was awarded to the latter as the lowest bidder. The Phototype Company now appear by counsel before Assistant-Secretary French, and ask that the contract made with the Graphic Company be set aside, on the ground that the bid of the latter was not in accordance with the terms of the advertisement, which called for bids 'at so much per thousand,' and that 'nothing' was not so much per thousand. The Secretary has not given his decision yet, but it is believed he will differ from the learned counsel of the Phototype Company."

PHOTOGRAPHIC CHEMICALS.—The danger attending the handling of chemicals used in the photographic business is greater than many would suppose, and it is a wonder that many more are not seriously injured. Some, in fact, are, but it is not generally known. We are led to these remarks by meeting with a very painful accident, but not serious, since our last issue, from opening an ammonia bottle. The stopper flew out with such force that the ammonia made tracks for our left eye. The only remedy was to make for the water tank, which we did by going it blind. This has caused us to switch off to the right eye for assistance in getting out this number of the journal, and have gone one eye on everything ever since. But we hope by our next to see stereoscopically correct again. Photographers cannot be too careful in handling acids, ammonia, ether, collodions, and other dangerous chemicals in hot weather, for an accident may happen, as it did to us, when least expected.—*Practical Photographer.*

A NEW MUCILAGE.—The *Journal de Pharmacie* states that if, to a strong solution of gum arabic, measuring $\frac{3}{4}$ fluid ounce, a solution of 80 grains of sulphate of aluminum dissolved in $\frac{1}{2}$ of an ounce of water be added, a very strong mucilage is formed, capable of fastening wood together, or of mending porcelain or glass.

To Correspondents.

H. H.—Tungstate of soda is dissolved and added to the solution of chloride of gold, in the same manner as acetate of soda is used. Follow the instructions of the formulae we have given in our *Year-Books*. 2. It entirely depends on the nature of the varnish as to whether you can easily remove it from a negative. If it be a spirit varnish, repeated washes of strong alcohol will remove it. But re-varnishing will often remove the dulness caused by "chilling." 3. Coffee used in dry processes is, of course, roasted. It is the same article which is employed for table use.

L. S.—We do not keep the dates in our memory, and have not the means of reference at hand. Our correspondent should make the search for himself, which he wishes us to make for him. Being from home, our reference books are not at hand.

H. VANDALEUR.—We are always desirous of helping correspondents as far as possible; but they should remember that this column is devoted to answering questions and giving advice on specific difficulties, not to teaching processes or re-stating formulae. It would be simply impossible to instruct you how to take "Ram-breads" in the space we can devote to "Answers." We have published many articles on the subject, both in the *News* and in our *Year-Books*: to these articles we must refer you for general hints. Remember that the principal characteristic of this style of portraiture is a prevalence of shadow or half-shadow. Use a concentrated light—that is, leave very little of your large skylight uncovered by blinds—and bring the sitter close under this concentrated light. Use thin translucent blinds over a great part of the glass, so as to secure half-lights, or effect the same end by the use of hand-screens in the manner we have recently described. In some cases the sitter may face the light with advantage, in others it is undesirable. A dark grey background will answer. 2. The lens you mention will, in many cases, answer well for card groups; but, of course, everything depends on circumstances. If there are many in the groups, a lens of longer focus would be better. A stop will (in groups) often be desirable to secure perfect definition; but it will, of course, increase the exposure. 3. The ordinary negative bath will, in many cases, serve for ferrotypes; but it often requires more nitric acid in a bath for ferrotypes than is desirable in a negative bath. We do not understand what you mean by using "plain collodion" for ferrotypes. A properly prepared positive collodion should be used. 4. We cannot give you any better formulae for a negative bath than those we have often repeated in the *Year-Books*, and to which you refer. Good results are as much dependent on care and skill as on formulae.

F. T. DAY.—The spots have the appearance of those caused by the particles of bronze used in what is termed "gilding" printing on cards. None of the cards sent is printed in gold, but they may have been in contact with cards which have been so printed. We have seen at times almost every print in a portrait album spotted through the presence of two or three with bronze printing. The carbonate is the best form for ammonia in the fixing bath.

D. TOLMAN.—There are various methods of photographing on wood for the engraver. It is difficult to say which is the best method. The use of collodio-chloride of silver, using a very powdery sample of collodion, answers well. Taking a collodion transparency in the ordinary way on glass, toning it with platinum, and then transferring the film, face downward, to the wood, after this, dissolving the collodion, leaving the black platinum image on the wood, also answers well. We do not know where you could obtain lessons.

J. C. B.—The microscopic photographs to which you refer are chiefly produced in France. We cannot tell you where you can procure them.

J. F. NEWLAND.—You wish us to assist you to secure better lighting than you have at present, but you do not send us any example of your present lighting, to enable us to suggest how it may be improved, nor do you say in what method you use your blinds. If you send us fuller information we will do what we can to help you, better than by simply answering your questions regarding Bigelow, whose method, as described, we do not quite follow. The only difference between calico and muslin is, we take it, that the latter is finer, thinner, and more transparent than the calico. We sent off the book as soon as your request to do so reached us.

A. CONTINENTAL SUBSCRIBER.—We shall be glad to hear from time to time of your success.

B. E. F.—Prints whilst toning should receive constant attention, to prevent them from sticking together, or floating to the surface, and so becoming unevenly toned, as the sample enclosed is. Use a pair of horn forceps for lifting them, and take care that the forceps are not used for any other purpose. The same attention is required whilst the prints are fixing.

A. THREE YEARS' SUBSCRIBER.—The simplest process you can adopt, if you are not familiar with the class of work, is to make a collodion enlargement on glass, and transfer it to your canvas, as we have several times described. Having produced and toned your transparency, place it in a large dish containing water to a pint of which twenty grains of citric acid have been added. This will loosen the film from the glass. When loose, pour off the acid water and rinse with clean water. Then lift the plate out of the water, and place a sheet of tissue paper the proper size on the film. Turn the edge of the film just over the edge of the tissue paper, and lift the whole away from the glass. In the meantime, your canvas should be at hand quite ready, and upon it you place the film and paper. Rub down carefully, and then lift the tracing paper away. The canvas should be prepared by cleansing from greasiness by sponging with a little fine soap and warm water, rinsing well, and finally sponging with alcohol. Finally, apply a three-grain solution of gelatine with a broad, flat brush, and allow it to dry. It is then ready to receive the collodion picture as we have described.

Several Correspondents in our next.

The Photographic News, September 7, 1877.**PHOTOGRAPHY IN AND OUT OF THE STUDIO.
THE VELOCITY OF LIGHT—THE PHOTOGRAPHS OF THE LAST
NORTH POLE EXPEDITION.**

The Velocity of Light.—M. Fizeau, whose name as an investigator of light is well known in the photographic world, has been followed up in his researches, it seems, by M. A. Cornu, so far as the determination of its velocity is concerned. M. Fizeau has made the subject of light quite his own, and, in the early days of Daguerrotype, he did much towards improving and elaborating the process. He it was who first of all distinctly comprehended the fact that so long as only one image could be secured by the Daguerrotype process, the application of the latter must be very limited. It was his endeavour, after an image had been once secured, to produce therefrom other duplicate images—a problem which Fox Talbot had already solved in his process, which permitted of the production of negatives instead of positives. Fizeau's Daguerrotype engraving process, by which he sought to convert the Daguerrotype plate into a printing block, from which impressions might be printed in the press, although a singularly ingenious one, turned out of little practical value, since it was impossible to produce half-tones by its means in any degree of perfection; and the strides made at the same time by the application of collodion and glass plates to photography at once placed M. Fizeau far behind, and he abandoned a line of research which, at one time, bade fair to ensure him considerable reward. But he did not forsake the shrine at which he had so long worshipped; he simply devoted himself to some other portion of the vast subject which he had made his own. This was to ascertain the velocity with which light travels, a matter which, as everyone who has studied light knows, is beset with peculiar difficulty. According to M. Fizeau's experiments, the velocity of light was 185,157 miles per second; and when we mention that, after some very elaborate researches undertaken by M. Cornu, this gentleman finds that the velocity is represented more accurately by 185,370 miles per second, we can only wonder at the accuracy with which M. Fizeau conducted his investigation. Unfortunately, in a delicate research like this, it is impossible to exclude errors of all kinds, and we must take, therefore, both the results of M. Fizeau and M. Cornu as approximate truths only; still they are both so near one another that we may, at any rate, conclude that light travels in any case at the extraordinary velocity of more than 185,000 miles per second. We have no such trustworthy data in respect to the velocity with which electricity travels, for in this case the estimates made by various philosophers differ widely from one another. Thus Fizeau estimates the velocity of the electric spark through iron at 62,100 miles per second, and through copper at 111,780 miles; while Wheatstone's results seemed to prove that the velocity was as much as 288,000 miles per second. Kirchhoff, the German philosopher, tells us that the motion of electricity in a wire where it meets with no resistance should be 192,924, which is the same as light *in vacuo*. Photographers may be interested to know how it is possible to determine the rate of travelling of so rapid a medium as light, and we therefore will try to explain the method adopted by M. Cornu in as few words as possible. There is a toothed wheel which revolves at a rapid and known velocity. A powerful ray of light, which may be termed pin-pointed, is allowed to pass through one of the niches in the wheel, and as the wheel revolves the point of light is obscured whenever a tooth passes. We will imagine the wheel at rest for a moment, and this ray of light shining through one of the niches. By having recourse to suitable lenses and a reflecting surface upwards at the proper angle, this ray of light is sent on a journey of 10,000 metres—in fact, from the Paris Observatory to the Fort Valerien, beyond the Paris fortifications. Arrived at

this station, the ray is reflected back again whence it came, and with such accuracy that it touches the wheel in the same spot that it emerged from. The wheel is now set to revolve, and when at its full speed it may be found that two or three teeth pass in the interim of the light being passed and received back again, when it remains only to be calculated how long these two or three teeth were in moving through space. As we have said, the rate at which the wheel revolves is well known, so that the time taken by that portion of it which is represented by two or by three teeth is easily found, and this corresponds with the period which the ray of light took to travel the 20,000 metres to Fort Valerien and back again. This was M. Cornu's plan of examining the velocity, M. Fizeau, in his earlier experiments, having recourse to a much more restricted field of operations. Still, with all this difference, there is, as we have seen, but very little to choose between the results of the two French philosophers, and they are far better agreed upon the velocity of light than others upon the velocity of electricity.

The Photographs of the last North Pole Expedition.—The Admiralty has been keeping its pictures of the last North Pole Expedition very close. Captain Abney tried his hardest to obtain some of the photographs to illustrate the interesting paper read early in the year before the Photographic Society; but the jealousy of those in office, or the red-tapism of government institutions, prevented a single result being shown to support the communication in question. This is rather hard, we cannot help thinking, seeing that the department over which Captain Abney presided at Chatham furnished much information and instruction in photography to the Arctic officers, and may be said to have placed them in a position to secure the results obtained. At last, however, Whitehall seems to have stirred in the matter, and now, about a year after the return of the expedition, a series of the views has been published under the supervision of Sir George Nares. As it was public money that enabled the pictures to be taken, it seems strange that the public should be kept so long waiting for a peep at the results, and even now, we understand, instead of the photographs being deemed public property, and put at the disposal of any one who would wish to purchase them, it is intended simply to strike off a very limited number of copies, and place them in institutions where practically the general public will never be able to get a view of them. Rumour says that only fifty copies of the pictures will be printed in all, and these will be distributed to the British Museum, South Kensington, and kindred institutions. There are among the pictures some which must prove interesting to disciples of the various sciences, as well as to the public generally. One photograph, for instance, demonstrated the discovery of coal in the Arctic, a solid mass of this valuable material, more than twenty-five feet broad, being depicted. Other pictures show very plainly the nature of the ice masses of which the frozen sea consists, and prove more than all the descriptions in the world how difficult it must be for sledges to make way over this sea of troubles. When we spoke in these columns, three years ago, of the advantages which must necessarily accrue from the use of the camera by the North Pole expedition, we felt sure that the results which would thus be obtained would prove among the most interesting relics of the expedition. And so they have turned out to be. The desolate wastes of snow and ice, the weary aspect of the horizon, the dull leaden hue of the ice-bound landscapes so graphically represented in many of the pictures, give a most graphic idea of Arctic travelling. Altogether, there are one hundred pictures, or rather more, in the series, which Captain Sir George Nares has selected to represent the experiences of the expedition, and we only trust that the Admiralty will in a short time be prevailed upon to permit any of the public, who desire to purchase copies, to have the same by paying the cost price of printing and mounting the pictures.

DISCOVERY OF OXYGEN IN THE SUN BY PHOTOGRAPHY, AND A NEW THEORY OF THE SOLAR SPECTRUM.

BY PROFESSOR DRAPER.*

At first sight it seems rather difficult to believe that an ignited gas in the solar envelope should not be indicated by dark lines in the solar spectrum, and should appear not to act under the law "a gas when ignited absorbs rays of the same refrangibility as those it emits." But in fact the substances hitherto investigated in the sun are really metallic vapours, hydrogen probably coming under that rule. The non-metals obviously may behave differently. It is easy to speculate on the causes of such behaviour, and it may be suggested that the reason of the non-appearance of a dark line may be that the intensity of the light from a great thickness of ignited oxygen overpowers the effect of the photosphere; just as if a person were to look at a candle flame through a yard thickness of ignited sodium vapour, he would only see bright sodium lines, and no dark absorption lines. Of course, such an explanation would necessitate the hypothesis that ignited gases such as oxygen give forth a relatively large proportion of the solar light. In the outburst of *T. Coronæ*, Huggins showed that hydrogen could give bright lines on a background of spectrum analogous to that of the sun.

However all that may be, I have no doubt of the existence of substances other than oxygen in the sun, which are only indicated by bright lines. Attention may be called to the bright bands near G, from wave lengths 4307 to 4337, which are only partly accounted for by oxygen. Farther investigation in the direction I have thus far pursued will lead to the discovery of other elements in the sun, but it is not proper to conceal the principle on which such researches are to be conducted for the sake of personal advantage. It is also probable that this research may furnish the key to the enigma of the D, or Helium line, and the 1474 K or Corona line. The case of the D, line strengthens the argument in favour of the apparent exemption of certain substances from the common law of the relation of emission and absorption, for while there can be no doubt of the existence of an ignited gas in the chromosphere giving this line, there is no corresponding dark line in the spectrum of the solar disc.

In thus extending the number of elements found in the sun we also increase the field of inquiry as to the phenomena of dissociation and recombination. Oxygen, especially from its relation to the metals, may readily form compounds in the upper regions of the solar atmosphere which can give banded or channeled spectra. This subject requires careful investigation. This diffused and reflected light of the outer corona could be caused by such bodies cooled below the self-luminous point.

This research has proved to be more tedious and difficult than would be supposed, because so many conditions must conspire to produce a good photograph. There must be a uniform prime moving engine of two horse-power, a dynamo-electric machine thoroughly adjusted, a large Ruhmkorff coil with its Foucault break in the best order, a battery of Leyden jars carefully proportioned to the Plücker's tube in use, a heliostat (which, of course, involves clear sunshine), an optical train of slit, prisms, lenses, and camera, well focussed, and, in addition to all this, a photographic laboratory in such complete condition that wet sensitive plates can be prepared which will bear an exposure of fifteen minutes and a prolonged development. It has been difficult to keep the Plücker's tubes in order; often before the first exposure of a tube was over, the tube was ruined by the strong Leyden sparks. Moreover, to procure tubes of known contents is troublesome. For example, my hydrogen tubes gave a spectrum photograph of fifteen lines, of which only three belonged to hydrogen. In order to be sure that none of these were

new hydrogen lines it was necessary to try tubes of various makers, to prepare pure hydrogen and employ that, to examine the spectrum of water, and, finally, to resort to comparison with the sun.

The object in view in 1873, at the commencement of this research, was to secure the means of interpreting the photographs of the spectra of stars and other heavenly bodies, obtained with my twenty-eight inch reflector. It soon appeared that the spectra of nitrogen and other gases in Plücker's tubes could be photographed, and at first some pictures of hydrogen, carbonic acid, and nitrogen were made, because these gases seemed to be of greatest astronomical importance, on account of their relation to stars, nebulae, and comets. Before the subject of comparison, spectra of the sun was carefully examined; there was some confusion in the results, but, by using hydrogen, the source of these errors was found out.

But, in attempting to make a prolonged research in this direction, it soon appeared that it was essential to be able to control the electrical current with precision, both as to quantity and intensity, and, moreover, to have currents which, when once adjusted, would remain constant for hours together. These conditions are almost impossible to attain with any form of battery, but, on the contrary, are readily satisfied by dynamo-electric machines. Accordingly, I sought for a suitable dynamo-electric machine and motor to drive it, and, after many delays, procured a combination which is entirely satisfactory. I must here acknowledge my obligations for the successful issue of this search to Professor George F. Barker, who was the first person in America to procure a Gramme machine. He was also the first to use a Brayton engine to drive a Gramme.

The dynamo-electric machine selected is one of Gramme's patent, made in Paris, and is a double light machine—that is, it has two sets of brushes—and is wound with wire of such a size as to give a current of sufficient intensity for my purposes. It is nominally a 250 candle light machine, but the current varies in proportion to the rate of rotation, and I have also modified it by changing the interior connections. The machine can produce as a maximum a light equal to 500 standard candles, or by slowing the rotation of the bobbin the current may be made as feeble as that of the weakest battery. In practical use it is sometimes doing the work of more than 50 large Grove nitric acid cells, and sometimes the work of a single Smee.

The Gramme machine could not be used to work an induction coil when it first reached me, because when the whole current was sent through the Foucault interruptor of the Ruhmkorff coil, making 1,000 breaks per minute, the electro-magnets of the Gramme did not become sufficiently magnetized to give an appreciable current. But by dividing the current so that one pair of the metallic brushes which collect from the revolving bobbin supplied the electro-magnets, the other pair could be used for exterior work, no matter whether interrupted or constant. The current obtained in this way from one pair of brushes when the Gramme bobbin is making 1,200 revolutions per minute is equal to 100 candles, and is greater in quantity than one would like to send through a valuable induction coil. I usually run the bobbin at 622 revolutions per minute, and this rate will readily give 1,000 ten-inch sparks per minute with the 18-inch coil. Of course a Plücker's tube lights up very vividly, and generally, in order to get the maximum effect, I arrange the current so that the aluminium terminals are on the point of melting. The glass, particularly in the capillary part, often gets so hot as to char paper.

As long as the Gramme bobbin is driven at a steady rate the current seems to be perfectly constant, but variations of speed make marked differences in the current, and this is especially to be avoided when one is so near the limit of endurance of Plücker's tubes. A reliable and constant

motor is therefore of prime importance for these purposes. A difference of one per cent. in the speed of the engine sometimes cannot be tolerated, and yet at another time one must have the power of increasing and diminishing the rate through wide limits. The only motor among many I have examined and tried, that is perfectly satisfactory, is Brayton's Petroleum Ready Motor.

This remarkable and admirable engine acts like an instrument of precision. It can be started with a match, and comes to its regular speed in less than a minute; it preserves its rate entirely unchanged for hours together. Moreover, it is economical, cleanly, and not more noisy than a steam engine. The one of two-horse power I have ran for six months, day and night, supplying water and air to the aquaria in the Centennial Exhibition at Philadelphia. At any time, on going into the laboratory, it can be started in a few seconds, even though it has not been running for days.

OLD TIMES.

DAGUERREOTYPING IN THE BACKWOODS.

BY GIBBON-FITZ.*

"THAT's the chap—him with the white hat, fat and short like our old sow. Stand back, boys, and let me talk to the image man. Hello, stranger, are you him?"

"Whom do you mean, my friend?"

"Well, now, I didn't say I was your friend, howsumever, we wants to know if you are the Doggery-type man that sent them big bills out here? Hold on, I'll show you one on 'em," at the same time diving his hand into his coat tail, he pulled out one of my large posters.

"I profess to be the artist, gentlemen, and shall be at your service shortly."

"Bill, you hear them big words? Send for Caleb's larnin book till we know what he's comin over us."

Such was the reception I received at a small town called Sovereignville, near the borders of Missouri, Arkansas, and the Cherokee Nation. The crowd consisted of a motley group of half-breeds and whites of both sexes, that came crowding round as I alighted from my wooden elliptic spring wagon.

Shortly afterwards I took a stroll over the town. It was what is generally denominated a "one-horse town," and I would think a tolerably small pony at that. Two stores, one grocery, a stable, and four dwellings made up the sum of its buildings. I was searching for a room for operations, and in passing I was accosted by an old chap with, "What are you a-hunting for, stranger?"

"Nothing but light," I replied.

"Why, you're not blind, I don't think; I see plenty of light."

"You don't understand me, my friend. I am looking for a room suitable for taking Daguerreotype pictures in—a room with a good light."

"Oh, I reckon you's the great little man what's a-gwine to take off our heads with a chimera. Maybe I can fix you off. My darter Polly's got a bedroom. Polly can gin up her bed and sleep on a pallet. You won't take pictures by night, will you, stranger?"

"No, not Daguerreotypes."

"Well, Polly axed when you come to get her fizzy-germy took, so you must close the bargain with her 'bout the room."

Polly and myself soon "struck a trade," and I began arrangements for operations. In course of a few hours I announced myself as ready to take likenesses of all who wished them. In a short time my room was crowded. All the cases for exhibition on the table were opened and reopened a thousand times; the contents of my trunk turned over and over, the camera scrutinized before and

behind. Thinks I, this is all talk and no cider; and I asked if there was any lady or gentleman present who wanted a picture? A dead silence ensued; then a titter. At length one of the chaps spoke up to his sweetheart, "Betse, 'spose you have your pretty taken?"

"No, Bill, you front the glass awhile, and see how it works on you."

"I golly," says Bill, "I'll try it. Is thar any danger of the machiues bustin, stranger? I've heard you've got an all-fired lot of chemicals and acids in thar."

"No danger in the world, sir. All you have to do is to keep still for a few seconds." I then began to place him in position—

"Hold on here, stranger—none of your steel-traps and triggers about my head."

"Softly, my friend, I am only placing your head in the rest for the purpose of keeping you steady."

"Hold on, I tell you; you're not a-gwine to screw me up; I'm not the sort to be screwed, I can tell you, and if you don't quit, I'll slope."

I then explained as distinctly as I could the nature of the operation, and Bill became easy. His position was taken again, and I was just about to draw the slide from the plate-holder, when he cried out, "Betse, whar's the meal bag?"

"Keep very still and quiet now, if you please," said I.

"Whar's the meal bag, Betse?" cried Bill again. "Stranger, there was a doggery-type man here from Maysville, that made Reuben Frother's face right black on one side, and several of their faces black the same way. Now, me and Betse fetched the meal bag along to whiten one side of our faces, so when the machine works on us we'll be the same thing on both sides." So, slap, slap, went the meal bag on the side of his face, and Bill agreed to be "dattered if both sides wouldn't be white now." I said not a word—in fact, I was amused beyond laughing, and quietly carried on the process. The whole crowd had great faith in the meal bag arrangement. The artist who had visited them had indeed only given them *half* pictures.

In a few moments the picture was produced. I did not show it to my sitter, for the reason that I hold it for Barnum, who when he beholds it will dance, shed tears of joy, and thenceforth regard me as his Magnus Apollo, his greatest benefactor.

After a good deal of trouble, I explained to my patrons that the black pictures were not the result of the camera, but of the operator, and that I would produce them pictures as white as they wanted.

At another trial (without the meal bag) I succeeded in a fine likeness of Bill, who exclaimed, on seeing it, "Stranger, you're the greatest dogman that's bin in these parts. Jump in here, Betse, and let's have you."

Betse sat down, and Bill wanted to look at her through the instrument. I permitted him, as soon as I got the focus adjusted.

"Look out, stranger," said Bill, when he peeped in, "your noggin's in danger. Turn that hogany box over—Betse is bottom upwards. I don't 'low sich jokes as this, stranger. Betse aint to be turned up that way. Over with her!"

"My friend," says I, "Miss Betse is in no danger. Her position is caused by the instrument," and after a considerable explanation, convinced him that I was not intending to make game of his girl.

Betse's likeness was obtained "right side up," and Bill was overjoyed. The crowd was highly pleased, and went away as the sun declined, with the promise to devote tomorrow to my services; and I thought that night, as I cast myself, wearied with the day's exertions, on my bed, "Jordan is a hard road to travel."

AN AMERICAN PHOTOGRAPHIC WAREHOUSE.

WE find in the New York *Commercial Pathfinder* a long and graphic account of the photographic warehouse of Messrs. E. and H. T. Anthony, which is probably the oldest warehouse devoted to photographic goods now in existence. As the article will interest many readers we reproduce it here:—

"Progress is the order of the day. But progress implies change; and photography, though one of the younger arts, has proved quite as susceptible of ceaseless modification and improvement as many of the older and less interesting ones. Many years ago, in the infancy of the then new discovery, an article appeared in the magazines, by Professor Oliver Wendell Holmes, who conceived the details of the preparation and manufacture of materials connected with photography by the above-mentioned house to be of sufficient importance to enlist the service of his graphic pen.

"Photography in that day was deeply interesting and delightfully novel, but, compared with the present, it was, as it were, but the embryo of future possibilities. To follow in detail the upward course of the art in all those fleeting years would be foreign to the purpose of these lines, though undoubtedly many of the advances made are due to superiority of the provided means and supplies, as well as to improved methods. Our object is rather to describe generally the manufactures and premises of the firm to-day in their several establishments in New York and elsewhere.

"In addition to the materials requisite for the practice of photography, there are many collateral manufactures more or less nearly allied with it; such, for instance, as the making of albums, the printing of stereoscopic prints and portraits, the manufacture of stereoscopes and the recently introduced graphoscope, the production of beautiful transparencies for the window (which have lately become so popular) and for use in the magic lantern, the making of velvet passe-partouts, frames, and cases as settings for portraits, and the manufacture of the magic-lantern in all its more modern excellence and variety.

"The manufactures specially connected with photography embrace those of pyroxyline, collodions, varnishes, and other compounds, a great variety of chemicals (which require to be exceptionally pure and determinate in character), the albumenizing of photographic papers, and the manufacture of camera obscuras, apparatus, and accessories of the photographic studio.

"It will be very readily seen that the successful production of all these varied materials requires correspondingly diversified knowledge and skill. Chemistry, mechanics, and a certain estimate of the necessities of the trade, are alike indispensable, and finally, a large endowment of tact and unremitting industry to mould these factors into congruous unity and use.

"Some of these results have only been achieved by a long and systematic course of experiments, especially in the combination of many photographic compounds and the fabrication of their components. So delicate and important are some of these, that the slightest deviation from a prescribed formula would result in ruin to reputation and severe loss. The duty of determining these proportions devolves upon Mr. H. T. Anthony.

"Besides the large and commodious buildings united at Nos. 591 Broadway and 164 Mercer Street, where those splendid products of the camera—photographic transparencies—are made, the Messrs. Anthony occupy five distinct factories, or workshops, two of them in New York city (one over the freight depot of the New Haven and Harlem railroad in Center Street, and the other over the premises of the Adams Express Company, at No. 65, Broadway), and three in West End, New Jersey, where a considerable parcel of land is held in reserve for future emergencies.

"In the Franklin Street factory (over the freight depot)

there are printing presses, binders' presses, cutting machines, &c. Here are seen printing and embossing of album covers in endless variety of styles and all stages of advancement. Some of the operations of these machines are very interesting; so also are those of the printing presses, which not only beautifully print the 'insides' for albums, but punch or perforate the openings at the same time. Here also are cut and trimmed immense quantities of straw-board, card-board, and paper for the various departments.

"THE FACTORY AT NO. 65, BROADWAY.

"In this spacious building (40 by 220 feet in extent, and on three successive floors) are seen crowds of busy hands. The lower floor is devoted to the selection, trimming, mounting, and labelling of stereoscopic views, the manufacture of velvet frames, and *passe-partouts*, photographic cases, stereoscopes, the gilding of albums, &c. In one direction may be seen a number of workers, male and female, old and young, with dexterous fingers fitting and filing, nailing and punching, gluing and uniting the various parts of the stereoscope—that simple little instrument which reveals so much. Of these there is a large variety adapted to every caprice. Still further on are others engaged in arranging, in tasteful form, those delicate velvet frames which, with their blue and violet and many-coloured trimmings, are so well adapted to the now-popular photochrome and similar pictures. Here, too, are made those charming little oval velvet cases, so nice for miniatures, and all the more staple goods in that line.

"Opposite are a bevy of girls assigned to the care of stereoscopic views. There is something fitting in this, for standing among these weird little waifs of the camera, they follow in almost fabulous succession, appealing with powerful effect to the imagination. First may come a representation of the streets of New York, then a view down the Bay, or a glimpse of the Central Park; then perhaps, the majestic Niagara, the Yosemite, our East River Bridge, or the Island of Juan Fernandez, the princely elegance of Paris, or a panoramic view of Jerusalem, the Holy City.

"Next above the space is mainly devoted to the albumenizing of photographic paper—one of the more important, if not romantic, sub-divisions of the business. The labour of mounting, or stretching and varnishing, of chromos is also assigned to this floor.

"The upper floor is mainly appropriated by the album makers. Here may be seen the process called 'album building,' by which the 'insides' are 'built up' from simple sheets of printed and perforated boards into albums of different sizes and styles, afterwards to be covered, and the edges gilded and chased.

"WEST END.

"From No. 65, Broadway, to reach their West End factories in New Jersey, it will be necessary to take the steam cars in Jersey City, and after a five-minute ride and a four-minute walk, we arrive there.

"The smaller building (30 by 35), with the large chimney, to the north of the inclosure, is wholly devoted to the manufacture of what is commonly known as gun-cotton, a soluble pyroxyline for the preparation of photographic collodions, together with some of lower grade for other commercial purposes. Here the carded cotton may be seen immersed in certain proportions of nitric and sulphuric acid at a high temperature, after which it is removed with glass rods to earthen tanks for cleansing. It is then removed to the drying room, another building (20 by 30), some distance westward, where it is spread on shelves to dry.

"Between the two last-mentioned buildings there is another (30 by 70), divided by a party-wall into compartments—one for the manufacture, bottling, and packing of

collodion and ether, and the other similarly for photographic varnishes.

"In the main building (50 by 80), the lower floor constitutes the laboratory, wherein the more important chemicals are made, as well as the refining of photographic residues, &c.

"The floor above is occupied for toning and fixing photographic prints, operations which require the exercise of much judgment. In the loft above are stored thousands of negatives; whilst the upper one is given exclusively to printing from these negatives. Skill, neatness, regularity, and order are indispensable in this department. From this building the prints are transferred to No. 65, Broadway.

"THE STORE, No. 591, BROADWAY.

"The business of this firm (or rather Company, incorporated April 1st, 1877) is now conducted at No. 591, Broadway, extending to and including No. 164, Mercer Street. The lower floor (front) is occupied solely with and for the sale of stereoscopes and views, lanterns and slides, and portraits of celebrities; the middle portion for the sale of photographic materials, and the rear for packing and shipping.

"The next floor above (front) is reserved for the sale of chromos, engravings, photographs, albums, and an almost endless variety of frames, mouldings, &c. It is elegantly fitted with paintings, chromos, transparencies, and kindred articles, and is a favourite resort for persons of taste and leisure.

"On the floor above are stored passe-partouts, frames, albums, and chromos, where they are also prepared for shipment.

"The upper floor is devoted to the making of photographic transparencies, a department for the finishing and framing of pictures, and a goodly assortment of larger frames.

"In the rear building, above the store, are, first, a room for the preparation of orders for chemicals, glassware, &c.; above are kept apparatus and materials for the photographer.

"In the upper loft are stored hogsheads and crates of porcelain ware, barrels and tiers of glassware, boxes of apparatus, &c., a portion of it being divided into a room for the preparation and arrangement of lantern outfits and experiments connected therewith.

"Immediately below the latter is a compartment reserved expressly for the purpose of making chemical analysis and experiments.

"It is impossible, in a brief sketch like the above, to convey an adequate idea of the extent or variety of details which this establishment has directly under its management; but there are many other departments, with large interests involved, which are engaged in the manufacture of the less important requisites of the trade exclusively for this leading house, and solely dependent on its patronage.

"Nowhere, perhaps, in either of the great centres of traffic can there be found so complete or renowned an emporium for the sale and manufacture of materials connected with the photographic art."

HOW TO PREVENT BLISTERING.

In spite of the many remedies for blistering which have been proposed, some photographers are still troubled with it. Here is a remedy given by a correspondent of *Anthony's Bulletin*, which is said not to fail:—

"We have at last succeeded in hitting upon a means which in all our trials has given the most satisfactory results. We think it a sure cure for blisters, and we hasten to advise you of it, viz:—

"The sheets after having been taken from the toning

bath are to be washed in clean water, and then put, if possible, each sheet separately, into a water bath, being mixed with three to five grains of C.P. muriatic acid to a quart of water. In this bath, kept in continual motion, the sheets are to float two to three minutes, and then to be washed again two to four minutes in clean water, to make them free from the muriatic acid. On hot days this washing is to be continued longer than on cool days. After this one proceeds to the fixing. Should the finished copies—an accident which will scarcely occur—show a yellowish tint, the sheets after the muriatic acid bath are to be drawn through a solution of liquid ammonia five grammes in one quart of water, during one to three seconds, afterwards washing the sheets once, and then proceeding to fix in the ordinary way. By this manipulation any alteration of tint is quite impossible."

RETICULATION IN CARBON PRINTS.

[MR. P. C. DUCHOCHOIS, an experienced photographer in the United States, writes to *Anthony's Bulletin* describing a cure for the troublesome reticulation in carbon prints. He says:]

I think that this communication to the *Bulletin* will be welcomed by all the licencees of the chromotype or carbon printing, for, to my knowledge, no method has been published by which the reticulations can be surely avoided. During this hot and damp summer I had, as well as everyone working this beautiful process, my good share of trouble to avoid this capital defect, in trying, without success, all that has been published by Liebert, Vidal, Lambert, the Autotype Co., &c. As this defect occurs only in warm weather, and is consequently mechanical, I thought that the remedy should be searched in other directions than those we were told to look for; and . . . I have succeeded in finding a process simple, sure, and, I think, new, by which the reticulations are impossible. It is simply to transfer the sensitive tissue on a glass waxed and collodionized, or well waxed only. I prefer the former. The excess of bichromate solution must be taken away with the squeegee, and no bubbles of air allowed to remain between the tissue and the collodion. The tissue is stripped off the glass when well dry, and only at the moment of printing, as it keeps better and remains perfectly flat to be laid on the negative. The bath should be at 2½ per cent., without ammonia, and at a temperature not exceeding 50°F. Immersion, two minutes. Many photographers have also found, during this summer, something new in the chromotype process; we all hope that ere long they will publish the results of their observations and researches.

[The Editor adds:]

We welcome from any quarter suggestions made for the purpose of meeting difficulties, whether in the carbon or silver process. We have no doubt that the trouble experienced in some quarters in working chromotypes in hot weather will eventually be overcome. We thank Mr. Duchochois for his important communication, and much commend the brotherly spirit evinced by our carbon workers, who are so willing to impart to others that mode of working whereby successful results may be attained. Will such of our readers as try this process be so good as to communicate the results?

TO REMOVE SILVER STAINS FROM FABRICS.—This process is especially successful in removing spots from materials which have been several times washed. First prepare a saturated solution of chloride of copper, dip the spotted piece in the solution, and allow it to remain some minutes, or according to the character of the stain. Then rub the part with a crystal of hyposulphite of soda. When neutral chloride of copper is used the colour of the stuff does not change. This process can be repeated.

COLOURING PROCESSES FOR PHOTOGRAPHS.

PERHAPS one of the most natural impulses which could occur to an artist on seeing the perfection of detail and drawing in monochrome which the photograph presents, would be the desire to add to perfect drawing the charms of colour; and it is probable that whilst the miniature painter's immediate occupation was destroyed by the advent and progress of photography, a greater number of colourists are now employed in connection with photography, than ever made a livelihood by painting likenesses. But painting on the photograph not only requires highly skilled labour, but perpetually risks more or less of alteration and hiding of the drawing in the photograph; and it is, moreover, at best, a slow and costly process. Hence there has been from the early days of photography a hankering after some process of colouring—something which should give results not altogether unsatisfactory, without the elaborate treatment of the artist painting on the picture, and something, moreover, not liable to hide or alter the photographic impression. A large number of allied processes of colouring the photograph have been devised, in almost all of which the drawing of the photograph was to be superposed upon crude colouring applied in various ways. A favourite method has been to make the photograph transparent, and apply colours crudely and brilliantly at the back of the print, or on another print to be placed in contact with the transparent print. This method has been extensively applied in different forms. In some cases the transparent photograph was a paper print, made transparent with wax or varnish; in some cases a collodion print; and latterly an unmounted carbon print. In some cases the colouring was applied by hand, and in others it was printed by lithography or other means. But the general principle was the same in all cases. M. Vidal's recent fine results have been obtained on this principle, and Mr. Woodbury has produced some fine imitations of painting, lithography having been called to the aid of both gentlemen.

One of the most recent applications of process to the colouring of photographs has been patented by Messrs. Lombardi and Co., and the public are invited to examine the results which can be produced at their galleries in Pall Mall and in Brighton. Of the nature of the process we have no information, as the specification is not yet published, and we fear that the patentees are in danger of making the fatal mistake of believing that secrecy and patent protection are compatible, and can both be made available. Of that, however, we shall be better able to speak when the specification is published. In the meantime we have pleasure in saying that, so far as the results are concerned, they are by far the finest we have ever seen produced by a process, and fully justify, by their

excellence, the intimation we have received, to the effect that whilst there is a method capable of protection by patent, the excellence of result depends on the application of the method by the hands of a skilled artist. The examples exhibited by Messrs. Lombardi are chiefly copies of the paintings of great masters, and are admirable in every way. The accuracy of drawing in such reproductions of course cannot be subject of doubt, being the work of photography. The colour has all the force and all the mature tone and richness of the masters represented. There is a singular absence of the garish rawness of the olograph copies of old pictures with which the art market has been flooded of late. The poikilographic oil paintings, as they are termed, are at once brilliant and mellow, forcible and soft, and fitted to please the most highly cultivated and critical taste. The method is applicable, we understand, and intended to be applied, to modern portraiture; and we believe it is the intention of the firm to undertake commissions from "the trade" on liberal terms. But of this form of application we can say nothing, not having seen examples. The subject is interesting, and the specimens are well worth a visit from all who have opportunity.

We have before said that some of the methods of colouring we first mentioned have been the subject of many patents. Notwithstanding this, it continues to form the basis of new patents at intervals, with or without modifications. We have before us a recently issued specification of a patent taken by Mr. H. E. Newton, a communication from M. C. Rousseau, of St. Etienne, in France. From the specification, which we subjoin, it will be seen that the superposition of a carbon print over a rough colouring, or the colouring at the back of the film, constitutes the supposed novelty. From the moment that a transfer carbon process was invented by Mr. Swan, it became obvious to any one familiar with these methods of colouring that the insoluble gelatine image produced would lend itself admirably to this style of finish. And in the first work issued on the subject—our own volume on Pigment Printing—we suggested that the touching out of defects should always be effected at the back, so that the finished print should not show the treatment with the pencil and pigment. The specification here is headed "An Improved Process for Obtaining Pictures in Colour, a communication from abroad by Cheri Rousseau," and is as follows:—

The object of this invention is to obtain pictures on canvas or other permanent backing in colours by the aid of the carbon photographic process in lieu of employing the skilled artist for producing such pictures. The process is applicable to all kinds of pictures, such as portraits, landscapes, still life, and the reproductions of paintings. In carrying out the invention a photographic carbon print of the object to be reproduced is first obtained, this print is then mounted on a temporary supporting paper in a reversed position, the photographic picture is then tinted with colours prepared with any suitable medium, but all colours will by preference be generally employed. The colours of whatever kind are thickly applied with a brush, care being taken to follow the details of the subject in their appropriate colours. When the crude colours thus carefully applied to the carbon print are dry, the whole surface of the picture is coated with some adhesive substance, and while wet it is transferred to the canvas or other permanent backing, and caused by gentle pressure to adhere thereto. The supporting paper which still covers the face of the carbon print is now to be removed in the manner ordinarily practised in the remounting of carbon prints, after which the coloured picture will be presented to view, the crude colours being toned down and blended with the tints and shadows of the photographic print. The paper for temporarily supporting the carbon print in reverse may be prepared with stearine, alcohol, and resin, or with caoutchouc dissolved in benzine; but papers of this kind being readily found in the market it will be unnecessary to describe their mode of preparation. It will be understood that the coloured pictures when transferred to their canvas or other backing may, if desired, be re-touched on the face to remove any defects in the photograph, and to give increased force to the lights and shadows of the picture. This operation, as it requires great skill and judgment, can only be entrusted to an experienced artist. Having now set forth the

nature of the invention of "An Improved Process for Obtaining Pictures in Colours," as communicated to me by my foreign correspondent, and explained the manner of carrying the same into effect, I wish it to be understood that under the above in part recited Letters Patent I claim, producing coloured pictures upon a canvas or other permanent support by applying colours in oil or other media to carbon photographs mounted on a temporary paper or other support, and attaching the same when dry to the canvas, and then removing the temporary paper support from the face of the picture.

THE COFFEE PROCESS AND EMULSION PROCESSES.

THE relative value of emulsion processes and bath processes for dry plates becomes a very interesting and important question. In simplicity, and in the philosophic character of the process, emulsion work may, we think, take precedence of most of the bath processes. But the more vital question is that of excellence. No process, however simple, easy, and philosophical, can for a moment secure preference if it be in any degree inferior in results to the old and tested processes. We have seen many results from emulsion plates leaving nothing whatever to be desired; and we have seen trials as to rapidity between emulsion plates and other dry plates, and even between emulsion plates and wet plates, in which the former undoubtedly bore the palm. But we have not hitherto seen any comparative experiments made with care, under test conditions, to determine the relative excellence obtainable by the different methods. We have received, however, a communication, which we subjoin, from a gentleman whose care and manipulative skill are beyond question, in which he records his experiences with emulsion plates as compared with coffee plates. Our readers will remember the high terms in which we have frequently mentioned the prints from coffee plates with which we have been favoured by Mr. J. H. Whitehouse, of Ouchy, Geneva. He has recently been trying some of Newton's excellent emulsion obtained in New York.* He is prepared to speak of its results favourably, especially as regards rapidity; but is compelled to record that, for excellence of result, it is not comparable to the coffee process he works, which has been fully described in our pages. This, he frankly admits, may be due to his mastery of one process and lack of familiarity with the other. It must be admitted that in this experiment the emulsion is tried by a high standard, as Mr. Whitehead's landscapes by coffee are only comparable to some of the best of such men as Russell, Manners Gordon and Henry Cooper. We subjoin his communication:—

"As Newton's emulsion appears to attract considerable attention at present, it may interest some of your readers to learn some particulars of its behaviour in the hands of an amateur.

"As you know, I personally am *hopelessly* prejudiced in favour of the *coffee process*; still, believing in progress, and that the future contains more than the past, I am by no means disinclined to giving a trial to new things (though, thus far, photographically, the result has not been such as to encourage me in this cause). Consequently, when in New York last spring, and seeing in the *Scientific American* a very favourable notice of Newton's Emulsion, I called at the Scovill Manufacturing Co., the agents for its sale, to make some enquiries regarding it. I was there referred to Mr. Price as being the gentleman best informed upon the subject, and he most kindly gave me all desired information, and showed me some beautiful specimens of work done by this process. I was so pleased with what I saw and heard, that I concluded to take a small quantity of the emulsion to Europe with me, in order to give it a trial, though, as Mr. Price suggested, it would be much better if I could first call upon Professor Newton, and see his own manipulation, instead of trusting to printed in-

structions only. I was, however, unable to do so; but simply following the directions which accompany each bottle, I have met with sufficient success to induce me to send to America for a further supply of the preparation.

"I have not, it is true, as yet succeeded in producing results which would bear any favourable comparison with the specimens shown to me in New York, nor such as could for a moment be compared with much that I have done by the 'coffee process'; still, *this proves nothing against the real merits of the emulsion*, as all deficiencies and shortcomings—in view of what Professor Newton has accomplished with it—are fairly attributable to want of experience or some possible error or omission on my part.

"I was most successful when using rather a smaller quantity of pyrogallie acid in the developer than is given in the directions—say three to four grains, instead of four to six to the ounce—but even then the negatives were wanting in brilliancy and vigour as compared with coffee dry or ordinary wet plates, and to know the probable cause of this difficulty I have written to New York for further information.

"The emulsion, which is snowy white, and of about the consistency of cream, flows most smoothly and readily over the plate. Nor when albuminized according to direction is there the *slightest risk* of the film slipping; and in these respects, as well as in its *extreme rapidity*, I should unhesitatingly say that the emulsion fully comes up to all that is claimed for it, while certainly nothing can well exceed the simplicity of its application. I hope a little more experience will enable me to send you some creditable specimen by this new process.—Yours truly,
"Ouchy, August 28th." "J. HENRY WHITEHOUSE."

FRENCH CORRESPONDENCE.

THE IMPORTANCE OF CLEAN PLATES—HOW TO POLISH THEM THOROUGHLY—THE GELATINO-BROMIDE PROCESS IN FRANCE—ODAGIE'S PAMPHLET ON THE SUBJECT—THE ADVANTAGES OF THE PROCESS.

IT cannot be too often repeated that the minor operations in photography exercise a vast influence upon results which are to be perfect, and for this reason the observations of a practical photographer so experienced as M. Boivin upon the cleaning of glass plates to be employed in the dry process must of necessity have an interest for the painstaking readers of the PHOTOGRAPHIC NEWS. I will therefore resume, for their benefit, the principal points of a communication just received from my estimable collaborateur upon the subject in question. The cleaning of glass plates is, without exception, the most toilsome manipulation connected with photography, and in dry processes it requires very particular care and attention, for any negligence may at once give rise to failure. In the first place the plates should be chosen free from scratches and air-bubbles, and, indeed, imperfections of any kind; the edges should be ground before commencing work, and the less perfect surface should be marked at one of the corners with a cross, so that when it comes to applying the film this should be applied to the more advantageous side. The method adopted by M. Boivin for cleaning his plate is then as follows:—The glass plates are first of all immersed in a strong solution of ordinary commercial soda; they are then washed in ordinary water, and plunged in a bath of nitric acid diluted with water, where they remain for about twenty-four hours. On coming out of this bath they are washed once again in pure water, and then covered with a thick mixture of chalk and water, which is applied by the aid of a bit of rag. This chalk is not removed until the plates are about to be employed; to effect this a few drops of a tincture of iodine is employed (a few scales or decigrammes of iodine being dissolved in one hundred grammes of alcohol), with which the chalk mixture is moistened. A woollen rag is then rubbed

* We believe it may also be obtained of Mr. Atkinson, of Liverpool.

over the plate to remove the chalk, and some tale is afterwards applied with another rag or tuft of wool, the glass being finally polished with a piece of flannel. It is important that the flannel and woollen rag should be first of all washed in a solution of soda, so that they may be freed completely of any traces of grease. When the plates are to be used, it is possible to assure oneself of their perfect cleanness by breathing upon the surface in the ordinary way, a camel-hair brush being passed over the surface to remove any dust particles. If the cleaning is to be perfect, it is necessary that the plate should not be rubbed too much; if too much friction is used, not only do you fail to clean the glass, but you render it, in fact, more dirty than before. The rag held in the hand absorbs perspiration from the fingers, which is subsequently transferred to the plate itself.

The gelatino-bromide process, which till now has not counted a single disciple in France, may, in a little while, acquire the favour it has already secured in England. An amateur, who has made use of the method with considerable success, has just published a very complete description of it, adding to his communication a translation in *extenso* of Mr. Palmer's memoir, which has already appeared in the PHOTOGRAPHIC NEWS of the 10th March, 1876. Another article on the same subject, by Mr. Kennett, also finds a place in the pamphlet. The whole forms a small volume, which has just been published by Messrs. Gauthier-Villars, in Paris. The author, who is, it appears, a magistrate and artist, has adopted the *nom de plume* of Odagir. He presents his readers with a résumé of the memoirs of MM. King, Bolton, Fox, Mawdsley, Stuart Wortley, Kennett, and Palmer, which have led to the improvement of the gelatino-bromide process, and have placed it in the advanced stage it occupies at the present moment.

The cleaning of glass plates, of which we have just spoken, appears to our author a very simple matter; it is sufficient, he assures us, to pass over the surface a dry linen rag and a little dry tripoli, and then to draw a camel's hair brush over them the moment the emulsion is to be applied. To remove the latter, washing in warm water is sufficient. The sensitive liquid, which is applied to the middle of the plate, is spread very easily by the aid of a glass rod, or even with the finger. The film adheres very tenaciously, and does not become detached on development. Contact with the fingers does not leave behind any stain or spot, as in the case of collodion. The adherence of the film is, in fact, so complete that varnishing may be dispensed with. The sensitiveness of gelatino-bromide plates being very great, the exposure in the camera must be a short one; a few seconds suffice, according to M. Odagir, to bring about what would require minutes in the case of all other dry processes. Foliage is admirably depicted by means of the gelatine emulsion, adds the author, and distance is rendered with exceeding delicacy. The development of the plates is very rapid, and, on the whole, the process is a very economical one, for the employment of ether is altogether suppressed, the vapours of which, moreover, are very unhealthy, if not actually dangerous. It will be seen that the author is a great enthusiast in respect to the gelatino-bromide process.

ERNEST LACAN.

A SELF-ACTING PRINT WASHING MACHINE.

BY W. A. NICHOLAS.

I SEND you a sketch of a self-acting washing machine I had made for washing prints, a description of which may be useful to some of my brother photographers. A is a dish to contain the prints, with openings each end to carry off the water. BB vessels to receive the water after running through the prints. CC shoots to conduct the water from top dish. DD self-acting syphons to draw the water off from bottom vessels. EE two short legs to keep the machine from rocking over too far. F stand. To set it in motion proceed as follows:—Place the prints in the

top dish; turn on the water; as soon as the water rises to one of the openings one of the shoots (C) will convey it to the opposite side under vessel; as soon as that gets suffi-

ciently weighted with water it will cause the machine to rock over to the other side, thereby giving the prints a good moving about; the water will then run out of the opening at the other end of the dish, and be conveyed by the shoot to the opposite end under vessel; while that is going on the syphon D draws off the contents of the now full vessel, then by lightening it ready to rise again as soon as the other fills; as each vessel fills and empties itself, so it rocks backwards and forwards. Mine has a fall of between three and four inches, which knocks the prints about with sufficient force to turn some of them over—it does not break them.

I would not be without mine on any account, as all I have to do is to turn on the water, and I know that about every two pints of water that runs through the prints gives them a good shake up. Mine is very simply made. The top dish, fourteen by ten by four inches deep, is made of japanned tin, as also the under vessels, and the frame of light wood working on a loose axle. As will be seen by the sketch, the syphons are let through the sides of the vessels, so that when it cants over the syphons become covered by the water, which, of course, causes them to act. Distance from axle to top of dish, eighteen inches; same from axle to outside edge of under vessels.

Should any photographer take the trouble to make one, it will fully repay him.

ON HARDENED GLASS FOR LABORATORY PURPOSES.

BY J. W. SWAN.*

"To supply me with flasks and beakers, almost as resistant of the destructive agencies of fire and hard knocks as cast-iron." That was the attractive proposal made to me a few days since by the representative of a company now working M. de la Bastie's process for hardening or tempering glass. Samples were provided, not of flasks and beakers, but of other vessels that would sufficiently illustrate their properties. I immediately, and with great eagerness, gave myself up to experiments with some of the vessels. Some of them are here to-night, and are at the service of the members for the purpose of experiment. The result of my experiments are at least interesting. I found that even in a very thick basin water might be boiled, by means of a naked flame strongly playing upon it, without fracture; that the hot vessel might, without harm, be lifted off the stand with cold tongs and set upon a cold plate of iron; that altogether it bore an amount of ill-usage that was extraordinary. Then I thought I would subject it to a severer test; I therefore only partly filled the basin, and allowed the flame to play upon a larger surface of the glass than was covered by the liquid, so that the margin of the basin might be heated above the boiling-point. I did this with the idea that pro-

* Read before the Newcastle-upon-Tyne Chemical Society.

bably under those conditions the temper of the glass might alter or be destroyed where the glass was more strongly heated, and if it was destroyed, that fracture would almost certainly result. The agent of the company said no, but the fragments—the results of two experiments of exactly the same kind—say yes. The character of the fracture is worthy of attention; you will observe that the bottom, which was covered by the water, is broken in small pieces like hardened glass, and that the rim has broken in larger pieces with sharp-cutting angles—in fact, like ordinary untempered glass. Possibly tempered glass may in some instances prove useful in the laboratory—for the much-abused water bottle, for example—but for general purposes of the analyst, in place of flasks and beakers of thin glass, the experience which I have so far had of it makes me very doubtful of its utility.

SPIRIT PHOTOGRAPHS.

THE *Springfield Republican*, an American journal, has a curious exposure of this fraud. It says:—

“Photographing spirits must be the highest reach of the art—far above the commonplace reproduction of mundane countenances and forms. It is a precious thing for a great many bereaved ones, who find in a faint, blurred image a perfect likeness of some departed friend or child. Moreover, it is slightly more profitable than plain photography, even if it is the most wretched work possible; and for eight dollars a dozen of common cards, and one dollar for each extra sitting, a popular spirit photographer can manage to live, and even bear to suffer the tender drain made upon his vitality by the spirit control. So, last week, thought a spirit photographer of Boston, but he has changed his opinion. This person has been notably successful in obtaining spiritual effects, and has successfully borne pretty careful watching by the regular photographers of Boston, who have agreed that they could discover nothing wrong about his performance. His fame spread abroad. Not a few Spiritualists in this city have obtained pictures of themselves with spiritual attendants at their sides; and he had been engaged to attend as a spiritual artist at the Lake Pleasant camp meeting. Now this is over.

“Last week, at the instance of prominent Spiritualists, Mr. Charles Moore, of Moore Brothers, called on the photographer one morning in the character of a man very anxious to get a spiritual picture. He couldn't feel satisfied with one trial, nor even with two, but, after the second, the gentleman remarked that unless he could be left alone a short time he felt very uncertain whether he could get any more spiritual effects; the fact was, Mr. Moore's presence weakened the influence. And, sure enough, the third and fourth trials were not blessed with any ghostly presence at all. The result of Mr. Moore's unremitting attention to the photographer's doings was a surprise to that gentleman. They had only a little conversation that day, but the next morning Mr. Moore revisited him in company with the Boston artist, Black, and had a more emphatic interview. On his inquiry Mr. Moore frankly told the spirit photographer he knew it to be a humbug, and proceeded to describe to him precisely what he did.

“Briefly, it is this:—He would take a transparency—i.e., a positive picture on glass—sensitize a plate, and place the transparency upon it, just kept from touching it by minute strips of pasteboard. Then, by means of the light of a gas-jet, he would project a faint dull image of the transparency upon the plate, then prepare the latter in the usual way, and place it in the bath for use. When any person desires a spirit-picture he shows them a clear, unused glass, which he proceeds to prepare chemically, and drop into the bath, but into another compartment from that in which the spirit negatives repose, the two lying so close together that only the very sharpest observation could pos-

sibly detect the fact. The glass he takes out of the bath and puts into the camera is, of course, that on which the ‘spirit’ is already projected, and when it is produced the sitter sees the phantom likeness beside his own, and, if he is a believer, finds no difficulty in recognizing it for that of some beloved one gone before. When Mr. Moore made his trial, the photographer had evidently two plates, and no more, prepared; if he had relaxed his attention and left the artist alone a minute, that would have sufficed to get another plate ready, for, as Mr. Moore has shown us, the light of a match is enough to develop a spirit picture to a sufficient distinctness.

“Before Mr. Moore had expressed his opinion on the matter, the gentleman had been induced to give his views on this spirit work. He is a tall, lantern-jawed, gaunt Yankee, of the down-East type, and, as he stood at the camera during the sitting, he held his head down and drew ever and anon a long, deep breath. On inquiry, he explained that a singular sort of feeling always possessed him at these times, he supposed from the presence of the spirits. Mr. Moore inquired how it was that, when the shadow on the subject was on the right side, the shadow on the spirit form should appear on the left. Well, the spirit photographer said, some thought the spirit stood beside the subject, but his belief was that the spirit gathered itself into the camera in minute particles, and ‘impinged’ upon the sensitive plate. Mr. Moore complimented him on the word ‘impinge,’ as remarkably expressive, but pressed his inquiry, and it was further explained that the spirits don't need light, as the mortal sitter does, but bring their own light, which was supposed to account for the erratic position of the shadows.

“When the whole of this fraud was laid open, and the spirit photo. found that he had been ‘taken in and done for’ by an expert in photography, he was probably as mad a man as ever made money out of the credulity of his fellows. His anger, however, was quite unavailing. The Spiritualists who had believed in him were as mad as he was, and he was compelled at once to cancel his engagement with the Lake Pleasant managers on penalty of being prosecuted as a cheat—a fate which may possibly overtake him yet. The *Banner of Light*, which, since the healthy example of the *Spiritualist Scientist*, and the death of its long-time editor, has taken to exposing fraudulent mediums of all sorts, will print an account of this exposure, and the spirit photographer will have to give up his remunerative business.

“The Moores, by the way, who are among the most accomplished photographers of the country, are also experts in ‘spiritual’ pictures, having made them in many different ways, and knowing very nearly every trick that it is possible to play with the chemicals, camera, and dark-room. This is not the first time that they have been instrumental in showing up frauds of this kind, and some of our readers may recall the exposure of one Evans, who, within these two years, made spiritual tin-types in this city. Evans gave no sittings to persons in the form. Spirits were his only game. He received the visitor who wanted the picture of some one ‘gone before,’ in a dark parlour containing a spirit-charmed camera. He went into a dark room and prepared a plate, which he placed in the camera. A black velvet pall was thrown over it. The seeker after a spirit likeness was directed to lay one hand upon the camera, while the medium laid one of his on the other side. In solemn silence the process of photographing the spirit went on. After some minutes Evans arose and went into the dark room. Then he fetched out the picture, always very dim, but interesting to the visitor. Now, the way he did it was extremely simple. He had an assortment of transparencies which, to avoid the chance of discovery, he carried in his pockets. He ascertained ingeniously, if he could, what sort of a presence the visitor expected, and turned out a child, a young woman, or some aged person, in accordance with the expectation. If it was

not quite satisfactory, he would talk of the changes and developments of the spirit world. But in all cases the pictures were taken by the same means—a brief exposure to light, such as a match would give, of the sensitized plate. How this thing was discovered by the Moores, and how the spirit photographer was found drunk at an up-town hotel, and compelled to leave town on a midnight train, is an interesting *dénouement*. He begged hard to take his camera, which he said was charmed, and which he couldn't replace in a year; but the indignant patron whom he had deceived wouldn't yield a whit, and still retains that magic camera and its velvet pall."

ROYAL CORNWALL POLYTECHNIC.—FALMOUTH PHOTOGRAPHIC SOCIETY.

THE Judges in the Photographic Department express regret to observe a falling off in regard to the number of exhibits this year. It may be attributed to the run of unfavourable weather that we have had in England for the past twelve months, which has been very much against landscape photography and all out-door operations. But at the same time there is a very important feature in the present exhibition that must not be overlooked, and that is the great skill that has been displayed, both as regards artistic feeling and perfect manipulation, which will at all times more than compensate for any falling off in numbers. Some of the productions this year are truly marvellous, and of the highest possible order, in both the professional and amateur sections.

The first in the catalogue was a very large composition picture, "When the day's work is done" (by H. P. Robinson, of Tunbridge Wells, being the finest we have ever seen exhibited by that gentleman), which has been awarded a first silver medal.

Messrs. Frith and Co., of Reigate, send some very charming productions of large size (about twenty by eighteen); the best is Trinity Chapel, Canterbury Cathedral, with the tomb of Henry IV., contrasting very forcibly with the generality of interiors even of smaller size, frequently very heavy through under-exposure; this one in particular is quite free from that fault; it is very soft, and at the same time brilliant and free from blemishes of any kind. To this picture has been awarded a first silver medal. This firm also send some others of subjects of local interest, and some Swiss scenery, which is very fine.

Mr. Reuben Mitchell has been awarded a first silver for a very clever artistic picture, "A Lancashire Mill Pool"—being very soft and brilliant.

Mr. F. Palmer sends some good illustrations of Swiss scenery.

Mr. E. Forhead sends four pictures. The best is a study of plants and flowers; the others are landscape subjects, possessing several good qualities.

Mr. J. Millman Brown contributes some very good studies; his best—the "Valley of Bonchurch, Isle of Wight"—has been awarded a first bronze medal.

Mr. G. H. Dew sends some good pictures of Stoneleigh Deer Park. The subjects are well chosen, but are somewhat over-toned, and do not do the negatives fair justice.

In the portrait department, Mr. G. Nesbitt, of Bourne-mouth, exhibits a very fine collection of portraits. A first silver medal was awarded for No. 640, a portrait study.

Mr. W. Gillard receives a first bronze medal for the study of a head.

Mr. B. Wyles sends several productions, of which we cannot speak very highly, owing to the careless way in which certain manipulations have been conducted.

Mr. S. Fry exhibits three composition pictures. The one of the Taxidermist is the best.

Mr. W. M. Harrison, of Falmouth, sends an enlargement of a group of children in carbon, which is very fine. To this has been awarded a special bronze medal.

Mr. Faulkner, of London, sends some of his well known

exquisite work. Owing to their late arrival they could not be entered for competition, which we very much regret. His "Dorothy" and "Simplicity" are perfect masterpieces of art, which have been reviewed by the London press, and of which we cannot speak too highly.

AMATEUR SECTION.

The exhibits in this department are far above the average. Mr. E. Brightman carries off the palm for his gems, the "Views on the Lynn," which remind us of the work of that eminent amateur, Mr. Russell Manners Gordon, and we think being equal, which is saying a great deal. A first silver medal has been awarded to him.

Following very closely are some productions of Mr. H. Manfield, of Northampton, which are but very little inferior to those of the last exhibitor; a first bronze medal has been awarded to No. 770, "In the Fern Glen."

The productions this year of Mr. F. M. Brownrigg, we think, do not do him justice, having seen work of his that we like better.

Mr. F. Beasley, junr., came out very strong this year, which shows that he is a very painstaking worker. We have examples by him of several processes. His rendering of (No. 723) "Ivy Bridge, Devonshire," by the collodio-emulsion process, is very fine, and has been awarded a first bronze medal. We must not omit to notice the productions of J. D. Radcliffe, which although small in size, are by no means insignificant. "Going on an Errand" and "A Quiet Nook" are perfect little gems in their way.

Mr. H. M. White exhibited some work stated to be photo-ceramics. We fail to see what part photography has played in these productions, and therefore we withhold our judgment.

The judges of the photographic department were Messrs. Wm. Brooks, Carne, and Lanyon.

PICTURE FRAMES AND THEIR MANUFACTURE

[MANY of our readers, especially those residing in the provinces, may find it convenient to know something of the manufacture of picture-frames. A few suitable tools, in the hand of a man having some facility in using them, will often improvise a useful frame, especially as excellent mouldings can be purchased ready for use. We extract the following instructions from the *Carver and Gilder's Guide*.]

"In the first place allow us to remark that without a good edge on your tools, you must not expect to produce good work. Try, not how much, but how well, you can do the work in hand, when, with practice, you will find that you will not only do it well, but get over a considerable amount in a short time.

"You will have many kinds of wood offered you to work on, and it will be expected that you will be able to make as good work with the hard woods as with the soft, and sometimes you may not succeed as well as you may wish, but oftentimes difficulties are overcome which at first seem insurmountable.

"As in many other things—making mouldings, mitreing up, mounting pictures, cutting glass, &c., requires care as well as skill, and a careless workman will spoil as much material and waste as much time as he is worth; therefore, make it a rule to be as careful as possible under all circumstances, when you will not have to reproach yourself, if an accident occurs, with carelessness.

"*Tools Required*.—The tools required by the picture-frame maker may soon be enumerated.

"*Mitre Block*.—This block is made to guide the saw in cutting up mouldings. It consists of a thick piece of wood glued on a good bottom, with saw cuts in it at an angle of forty-five degrees, so that the moulding, when cut off, will form a square frame. Eighteen inches long will be found a convenient length. See Fig. 1.

"Shooting Board.—This board is made with a ledge screwed on at an angle of forty-five degrees, and a flat run

Fig. 1.

Fig. 2.

for the plane laid on its side. The use of the shooting board is to 'shoot' or plane the ends of the mouldings to bring the mitres close together. See Fig. 2.

"Shooting Planes.—Planes about fifteen inches long, and three and a-quarter wide, without handles, the plane iron without a guard, used for shooting the ends of the mouldings on the shooting board.

"Saws.—Those used for cutting up mouldings are called tenon or back saws, and are supported at the back by a piece of brass or iron, to prevent the thin blade of the saw from bending.

"Hammers, various sizes, and not too heavy.

"Chisels, different widths, *Brad-awls* and *Gimlets*, various sizes.

"Turnscrews, large and small.

"In addition to which a few small tools, such as pincers, scissors, punches, squares, &c.

"There must also be cut brads, from half-an-inch to three inches long, picture rings of all sizes, nails, screws, &c.

"Glue is also used, and as its strength is dependent upon quality, we will give a little information upon the subject, as the strength of the work is only secured by a good article.

"Glue.—Glue, an inspissated animal jelly or gelatine, is principally prepared from the parings and waste pieces of hides and skins, the refuse of tanneries, and the tendons and other offal of slaughter-houses. These should be carefully preserved from damp, being very liable to decomposition. When required for use they should be steeped for about fourteen days in slaked lime mixed with water, and then drained and dried. Before being converted into glue, the materials are generally steeped in weak milk of lime, well rinsed in water, and exposed to the air for twenty-four hours. After this they are placed in a copper boiler, two-thirds filled with water, and furnished with a false bottom, perforated so as to prevent them from burning, and as much piled on as will fill the vessel. Boiling is continued until the liquor, on cooling, forms a firm gelatinous mass. The clear portion is then run off into another vessel, where it is kept heated by means of a water-bath, and allowed to repose for some hours to deposit, when it is run into the congealing boxes, and placed in a cool situation. The next morning the cold gelatinous masses are turned out upon boards, wetted with water, and are cut horizontally into thin cakes with a stretched piece of brass wire, and then into smaller cakes with a moistened knife. These cakes are next placed upon nettings to dry, after which they are dipped one by one into hot water, and slightly rubbed with a brush wetted with boiling water, to give them a gloss; they are lastly stove-dried for sale. During this time the undissolved portion of skins, &c., left in the copper is heated with fresh water, and the whole operation is repeated again and again, as long as any gelatinous matter can be extracted. The first runnings produce the palest and best glue. In applying glue, the hotter the glue the

more force will it exert in keeping the united parts together; it should therefore be applied immediately after boiling. Glue loses much of its strength by frequent re-melting. (Glue should be purchased in dry weather, for that which is then soft is not of so good a quality as that which is crisp. The most transparent is the best. Good glue, if immersed in water for two or three days, will not dissolve, but swell; if of inferior quality it will partly or wholly dissolve. Again, that glue is the best which, being dissolved in water by heat, may be drawn into the thinnest filament, and does not drop from the brush as oil or water, but when falling extends itself into threads. Glue made from the skins of old animals is much stronger than that of young ones.

(To be continued.)

Correspondence.

REFLECTED LIGHT FOR SHORTENING EXPOSURES.

SIR,—Will you or some of your numerous correspondents inform me for what reason stops in lenses are black; why not have them white? Accident usually leads to many discoveries and improvements. I do not suppose what I am about to relate has never been adopted before in an emergency; but still I think what I am about to describe is very suggestive. I had set my mind on photographing a very beautiful subject, which was varied with water, trees, and with dark masses of foliage, scrub, ferns, tall grass, in the foreground—the make-up of a very fine picture. The difficulty was to get a still day. A fine morning tempted me to make the attempt; but, as usual, the gloom came on before I had fixed my camera. I waited patiently for more than an hour; the light improved, but when a gleam of sun shine appeared, the wind disturbed the foliage. At last a lull in the breeze came, but no sun. I took off the cap; but in about two minutes the wind put a stop to all further exposure, so I put up my instruments and left. As my plates are large (18 by 16 inches), I did not expect to have more than an outline of a picture; but on developing I had a good one in parts—water, foreground, and distance all well defined, full of detail; but the trees were faulty in the shadows, so I determined to try again on the first favourable opportunity, which soon occurred. This time all was sunshine, with a white cloud in front of the camera, so I concluded ten minutes would be ample time to get a fully exposed picture; but, to my astonishment, when I had developed my plate, it was as much under-exposed as my former plate, with two minutes in a gloomy light.

The same day I made a journey of twelve miles to photograph a long and smoke-begrimed building in the centre of a large town. When I had my camera fixed, I found I had forgotten my case of stops; to return for them was out of the question, so having a large business card with letter press on both sides, I cut it to the size and shape for a stop, then cut a jagged hole, three-fourths of an inch in diameter, in the centre, placed the card in the space for the stops, exposed ten minutes in the sun, and a second plate about five minutes. Arriving at home, I was anxious to test my plates. They were clean, and full of detail, when developed. This little incident rather shook my faith in black stops.

But to return to my charming spot of previous failures. Another favourable day came, which enabled me to make a third attempt, which was very successful. I exposed my first plate with a black stop, and to be quite sure of having a fully exposed picture I gave it forty-five minutes, and without moving the camera a second plate, with my before-named white card stop, fifteen minutes. Both plates were good; but the second is very superior, being full of fine detail in both the light and shadowed parts of the picture. The lens I used is Dallmeyer's patent rectilinear, with the small stop (three-quarters of an inch in diameter).

RUBEN MITCHELL.

Talk in the Studio.

PHOTOGRAPHING INTERIORS BY MAGNETUM LIGHT.—We have received from Messrs. Barony and Co. some very good photographs of the interior of Scarborough Aquarium. Few tasks could be more difficult to attempt, both on the score of darkness and the nature of the subjects, but the difficulties have been fairly combated, and the results are good.

ROYAL CORNWALL POLYTECHNIC SOCIETY.—During the meeting of the Society in Falmouth, this year, a lecture was delivered in the Polytechnic Hall, on "Photography," by Mr. Brooks, one of the vice-presidents of the South London Photographic Society, Mr. N. Carne in the chair. The object of the lecture was mainly to introduce and explain the most recent inventions in the photographic art, both in the camera and lenses and the photographer's stand, and the chemicals necessary for the preparation of plates, as well as an entirely new apparatus for the generation of oxygen gas. The camera was remarkable for its compactness and adjustments, while its simplicity in packing and its strength would have been recommendations in its favour even were it not that by means of it photographs, whether landscape or otherwise, could be taken with greater facility and free from the distortion owing to the nature of the adjustments of most cameras in use. The lecturer then explained what is known as the emulsion process; that was, the nitrate of silver and the bromides were mixed with the collodion, and so doing away with the nitrate of silver bath. The plates could, therefore, be used either moist or dry, and their long-keeping qualities, both before and after exposure, were much improved. The negatives produced by this process were not only finer, but did not give those violent contrasts sometimes seen in the ordinary wet process with the bath. Mr. Brooks dissolved his pyroxylene, added bromide and silver, and prepared an emulsion in presence of the audience, and subsequently exhibited negatives and transparencies on the screen to the great delight of the audience.

COLORING BORAX VARNISHES.—It is well known that an aqueous solution of borax is able to dissolve shellac, forming a kind of varnish to which any desired color can be imparted by mixing with pigments. Major Dr. Kahl, of Dresden, has communicated to the Dresden branch of the Saxon Society of Engineers the results of a large series of experiments made with these varnishes. He reports that they are very cheap, and dry very quickly, but they scale off from wood too easily. When this varnish is colored black with India ink and applied to paper, it possesses a fine gloss; but other colors, especially carmine, when mixed with this solution, acquire an impure shade, and many pigments cement together in this solution, forming a hard and totally useless mass. The black shoe polish sold for ladies' boots is often made by adding some black pigment to this shellac solution. For bronze boots, roseanilin may be dissolved in any alcohol varnish. —*Scientific American.*

To Correspondents.

FEARLISTED.—The case you describe is very annoying indeed, there can be no doubt, and also very unfair, but we do not see any simple remedy. How far you may have a remedy at law we cannot say, as that is a question for a lawyer. We cannot undertake to give an opinion upon whether the offender is, or is not, actionable.

W. B. B.—The method of making a photograph transparent, and colouring it at the back, is very old, and has often been described in our pages. The modification of this method, which has recently been revived in America under the name of *Photochrome*, has been described in our pages within the last few months. We have not heard of its recent introduction into this country. It has not been patented, nor do we see that it could be, inasmuch as the method under various modifications has been practised and even patented in this country many years back.

HARLOT.—It is very difficult to dissolve silver in alcohol unless you go the right way to work. By adopting the following plan we have found no difficulty. Take the proper quantity of nitrate and bruise it to powder in a Wedgwood mortar. Then add a little alcohol, and pound the silver with it into a creamy paste. Add a little more alcohol, and again pound. Then pour off as much as you can of the clear solution, add a little more alcohol, and again pound, and so until the whole is dissolved. If you are using strong alcohol, at all near to absolute, you may add to the mixture in the mortar a few drops of distilled water. We have generally succeeded in this way, without any boiling of the solution, although, of course, a little heat aids the operation of solution.

W. REYNOLDS.—We presume that you mean a collodion transparency, although you do not say so. To aid in transferring a collodion transparency to paper, it is desirable that the glass should be waxed. A piece of good plate glass should be used for taking the transparency upon; and if it be thoroughly well cleaned the film will leave it without difficulty. Treating the plate with wax is, however, an aid. Place a piece of pure bees-wax in ether, which will dissolve a portion of it. Pour a little of this on the well cleaned plate, and then polish it off, leaving none, apparently on the surface. The film will, as a rule, leave glass so treated without any difficulty. There have been various articles in the *News* and *Year-Books* on the subject. Articles on enamelling prints will also give you the information. The only method we can suggest for securing a sale for the printing-frames is to advertise them in the *News*.

B. A.—There are publishers of photographs in London through whom photographers wishing to sell to the public generally distribute their works. The largest publishers in this way are Marles & Co., Bohe Square. Apply to them with specimens of the work.

JOHN SMITH.—The horny repellent character of your collodion film is the sole cause of the trouble, and we fear that you cannot effectually get rid of the trouble without getting rid of that repellent film. There are various ways of doing this. The legitimate method, unfortunately, is not always available. It consists in using the collodion older and ripier. The same collodion with age will be all right. If you have none ripe enough, perhaps you have a little of an old and somewhat powdery or rotten sample, which, added to that in use, will modify it. The addition of a drop or two of distilled water to each ounce, and shaking well, is often an improvement. Failing the adoption of these methods, there are other palliatives. Reducing the strength of the bath will do something. Plunging the plate in the bath before it is too much set is also useful. Re-dipping the plate after exposure is sometimes a remedy. But if the bath be acid, this is dangerous, as it sometimes injures the image. In some cases the addition of glycerine to the bath answers; but we do not like additions to the bath, which often involve risk.

SEVER.—If we were building a studio we should adopt the old-fashioned oblong rectangular building with ridge-roof. Glass in roof and sides to within about six feet at each end, which portions, as well as the ends, should be opaque. We should have the largest portion of glass in the north side, but should not entirely exclude it from the south, which could be kept covered with blinds in sunny weather. But as so much dull weather prevails in this country, we should have south light available when necessary.

HOW.—Nelson's gelatine is generally used. A special quality for photographic purposes is prepared by Nelson. 2. We do not clearly understand what you mean by the "best transfer paper for drawing or sketching, to be copied on sensitive paper." Do you wish to use the drawing as a negative from which to print on sensitive paper? If so, you will see that the fact of its transparency interposes a difficulty in using it as a negative unless you make the portions to print white very opaque by using a dense pigment in drawing. Good tracing paper or tracing cloth is the best transparent material for drawing on. A tube of orange chrome, as sold by artists' colourmen for use in oil painting, added to a few ounces of spirit varnish, will make a good non-effluvia varnish for drawing negatives on glass with an etching point. Bates' black varnish will also answer well.

W. A. NICHOLAS.—It shall appear in *Year-Book* in due time, and in the *News* at once.

J. HENRY WHITEHOUSE.—Many thanks for interesting experience with emulsion, and also for charming prints from coffee plates. The fresh view of Chillon is very interesting. Your success with coffee plates scarcely becomes a fair ground of comparison, perhaps, with the emulsion, as we have rarely seen results even with wet plates, from the most skilled hands, which would compare favourably with them. We are anticipating with pleasure your formerly promised hints on "Boudoir Photography," which we some time ago promised to our readers.

W. PARRY.—No prints have arrived. Your project is, we think, a good one, and ought to command success.

A. SCHOFIELD.—We may say at the outset, in general terms, that your work is very good for a beginner. There is room for improvement in the lighting in some cases. No. 2 is best in this respect. A direct light a little to one side is generally most effective, and a general diffused light is least satisfactory. The exposure is generally about right, but there is in some cases a slight tendency to over-exposure. As a rule, they are sharp enough. Examine good work whenever you see it, and study the posing and lighting.

W. B. DINNIE.—The only cause to which, from their appearance, we should attribute the spots, is the particles of bronze from coiled gold printing on cards. Can you find any trace of such printing on the other cards amongst which these have been kept? We see no reason to suppose that they are due to any fault in the manipulation, the paper, or the starch.

Several Correspondents in our next.

The Photographic News, September 14, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

THE USE MADE OF PHOTOGRAPHY BY CONVICTS AND BY COURTS—TRANSPORT OF COLLODION—POPULAR ESTIMATE OF A PHOTOGRAPHER'S ABILITIES.

The Use made of Photography by Convicts and by Courts.—We have several times pointed out in these columns the important post which it behoves photography to fill in connection with legal matters. No copyist can be so precise, no draughtsman so exact, as the camera when it comes to making a *fac simile* of a document or sketch, and to us it is simply astounding that after all these years our law and police courts should not have made more use of photography. A month or two back we published a very interesting account of the way in which they manage these things in France, or rather in Paris; the use to which the French police is putting photography is day by day becoming greater, but with us it is not often that we hear of photographs of documents being offered as evidence. And yet we pride ourselves a good deal upon the thoroughness of our trials, and upon the accuracy of evidence. It is, we repeat, almost inconceivable why the use of the camera is not more frequently resorted to. Take, for instance, the present *cause celebre* concerning the detectives and the Turf frauds. How many times have the counsel for the prisoners asked to be furnished with such and such documents, and the prosecution promised copies, which are, we suppose, to be made by some clerk or official in the Treasury? Will not copies made like this be well-nigh useless one way or the other? In most instances it is a question, in these documents, not of the words, but how they are written, and whether they are in the handwriting of one or the other of the prisoners. Now it is just as easy to identify writing from a photograph of a document as from the original itself, and we have no doubt that experts such as M. Chabot would have as little hesitation in pronouncing an opinion upon one as upon the other. When a document is stated in evidence to be in the handwriting of an accused person, it is of small avail for the legal adviser of that person to have placed in his hands a pen-and-ink copy of the document. If he has not the original to deal with, or a photograph of it, there is little use of his having anything at all. Again, as the identity or non-identity of writing is, after all, a matter upon which everybody is in a position to form an opinion, it seems to us that when such a point involves a serious charge, the jury should have every facility given them to form a judgment of their own, independent of that offered by an expert in the witness-box. This opportunity they could enjoy one and all, were photographic prints at hand of the document under dispute, prints which would demonstrate every up-and-down stroke of the writing, every chance or uncertain mark of the pen. The cost of preparing photographic records of this kind, especially if the Treasury possessed a photographic establishment of its own, would be simply nominal. With a copy in the hands of the judge, the counsel, and the members of the jury, there would be no occasion for passing the document from one hand to another, no chance of its being lost or mislaid. "I believe," said one of the witnesses in the trial to which we have just alluded, "that this document is in the handwriting of the accused, but from that word to this word the writing is in a feigned hand." Such a statement leads, of course, to a constant passing to and fro of the important paper, and yet it is impossible for any one under such circumstances to examine and criticise the opinion given with proper care and deliberation. And while on this subject, we cannot help remarking that while the law is so slow, apparently, in making use of photography in this connection, those engaged in the Turf frauds, Messrs. Kurr, Benson, and Co., seem to have been quite alive to the value of the art.

Several times during the examination of these convicts did it transpire that communications received from the detectives implicated, if returned to the latter, were first of all photographed, so that the swindlers always retained in their possession sufficient to prove what letters had passed between the parties. The convict Kurr, when he returned a letter, retained a photographic copy of it, in order, as he said, that he should still hold some check over his former friends. We certainly have not as yet exhausted the applications of photography in connection with the production of *fac simile* results, and certainly it is in making copies of handwriting for verification wherein lies one of the most valuable uses to which the camera can be put in a court of law.

Transport of Collodion.—The German photographers are calling out—and with some reason, apparently—on the subject of the transport of collodion. They say that all sorts of explosives are suffered to be carried by sea and land; and why, they ask, should not this universal requisite of photographers be conveyed in like manner? Not only is it permitted to transport gunpowder and rockets, but dynamite and gun-cotton even, the principle of collodion, will be received by railway companies and carriers who object, however, to have the same material in the form of a liquid upon their premises. Or, rather, it is not the companies, so much as Government that objects. With us pretty well the same difficulty is met with, although in not so exaggerated a degree. In this country, certain companies refuse to have anything to do with gun-cotton, and therefore the absurdity of the comparison falls away. But collodion is everywhere regarded with such distrust that it is only under much protest that it can be shipped or conveyed by rail in England. Manufacturers have for some time past complained of the strict and almost impossible conditions that have to be fulfilled in sending collodion from one place to another, and many have been the petitions and prayers made upon the subject to those in authority. We are therefore in a fair position to sympathize with our German brethren, who seem to experience a difficulty in getting this important product carried about at all. We can only wish them a speedy release from their ills, and hope that Government, by reason of the comparatively small quantities that are usually transmitted, will see fit to extend such privileges, at any rate, as are enjoyed in connection with the transport of dangerous explosives.

Popular Estimate of a Photographer's Abilities.—A landscape painter wrote us the other day a very frank note. He had a difficulty in getting figures now and then for a foreground, and thought that if he had a camera to secure some of the rustic beauties he met from time to time, such photographs would come in handily for the purpose. Was there much trouble in taking photographs, he asked, and could anyone who knew anything at all about the matter secure good pictures? His idea, like that of many other people, is that the camera is a sort of machine, of which the handle has to be turned; and, if you have only the strength to do this, cabinets and cartes, as the case may be, fall out at the other end. Our answer was, of course, very simple. It was that photographs can undoubtedly be secured by anybody after an hour or so of tuition; but that, like most other pursuits, he who knew most about it secured the best results. If he wanted simply outlines and nothing more, there was no necessity for him to learn much; but if he desired to take rustic pictures like a Rejlander or a Robinson, then there was a good deal still before him. We quote the matter as an another instance of the estimation in which some people hold a photographer's abilities.

COLOURED MINIATURES ON CONVEX GLASSES.

A STYLE of portrait which has attracted much attention in America under different names, as *Photochrome*, *Oil Photo-Miniature*, &c., is described by Messrs. Rice and Thompson,

of Chicago. Some of our readers have recently asked for details, and although an account of these pictures appeared in our pages some time ago, we think it may interest some of our readers if we repeat the details as given by the firm in question in the *Photographic Times*. The details are as follow:—

If the print you desire to use for the miniature is mounted, place it in clear water, leaving it immersed until it separates from the card. Having your unmounted print ready, cut it a little smaller than the convex glass you are to mount it on. You will have prepared in a convenient vessel a little thin starch paste. Have your convex glass perfectly clean; wet the print, and then blot off the surplus water; paste the face of the print with the starch preparation, also covering the concave or hollow side of the glass with the same, using great care to work the paste smooth, both on the print and glass; lay the print on the glass, the prepared surfaces together, and proceed carefully to work the bubbles out with the fingers, after which lay two or three thicknesses of some soft, tough paper on the print, and with an ivory paper-knife, or flat stick, with curve about the same as the concave surface of the glass, work the print down to the glass, forcing out all the air; work from the centre of the glass toward the edges, and with great care, using very light pressure to avoid breaking the glass. The mounting of the print should be done quickly, as the paste dries very fast. When perfectly dry pour on a little castor oil, taking a small piece of fine sponge, and gently rub the oil over the whole of the surface of the print. Use oil freely, in order to saturate the paper; when perfectly translucent, take a small piece of fine sponge and wipe off the surplus oil. Your picture is now ready to apply the colour to the eyes, which is the only part of the work done directly on the print. Having coloured the eyes, take some narrow strips of thin cardboard, and with the mucilage paste the strips on the concave surface, as near the edge as possible; this is to keep the two glasses separate, and prevent the spots which frequently occur when the second glass is laid directly upon the oiled print. Having the strips of cardboard set, take another convex glass, perfectly clean, the same size as the one having the print; place the two together, putting the convex surface of the second glass into the concave surface of the one having the print attached. This clear glass, when in place, receives the colour for hair, complexion, drapery, and background. The colour can be removed wholly, or in part, from the glass on applying a little turpentine with a cloth. Any mistake in laying the colour can be easily and quickly corrected as above. Having applied the colour, back up with a piece of card, and with some strips of the adhesive paper, moistened *a la* postage stamp, or with a brush dipped in clean water, bind glasses and back together, and miniature is ready for framing.

OIL COLOURING FOR PHOTO-MINIATURE.

Eyes.—The colour for the eyes is applied directly upon the prepared photograph; use brush No. 3. Blue eyes, use Prussian blue mixed with a little ivory black. Brown eyes, use Vandyke brown. Grey or hazel eyes, Prussian blue mixed with Vandyke brown and silver white.

The colour for flesh, hair, drapery, and background is applied to the concave surface of the clear glass, which is placed over the mounted print.

Flesh.—Use vermilion, silver white, and chrome yellow, mixed to suit. For children, use rose madder or carmine in place of vermilion. For dark complexion dull the colour by adding Vandyke brown.

Hair.—For blonde hair, use half yellow ochre and Vandyke brown. For lights, use Naples yellow. Brown hair, Vandyke brown. Black hair, ivory black, silver white, adding a little Prussian blue. For grey hair use silver white, Naples yellow, black, and a little Prussian blue.

Drapery.—Whatever colour suits.

Background.—Your own judgment will suggest the proper colour to use.

To change the work in any way, take a small piece of cloth, dipped in turpentine, and remove the colour.

TO PREPARE STARCH PASTE.

Take a heaping spoonful of the starch, put into two ounces of cold water, in a tin-cup. Stir until dissolved, then bring to a boil, stirring constantly. If too thick, add boiling water."

FRENCH CORRESPONDENCE.

THE PHOTOGRAPHIC ARCHÆOLOGICAL SOCIETY OF FRANCE—ITS EXHIBITION AT HAVRE—ON PREPARATORY FILMS—THE ADVANTAGES OF ALBUMEN AND RUBBER SOLUTIONS FOR ACID AND ALKALINE DEVELOPMENT.

ON the occasion of the Congress of the Association for the Advancement of Science, which has just been held at Havre, the French Archæological and Historical Society, which busies itself with the preservation of photographic record of monuments, &c., conceived the happy idea of instituting an exhibition. The Society I speak of was founded in 1876, although many of its members have individually for some time past occupied themselves with the objects of the body. On the present occasion the Society desired to show visitors coming from all parts of Europe not only pictures of some of the more interesting monuments about the country, but also to show how far photography helps to record such objects, and how useful it is also to the archæologist, the geologist, the geographer, and the astronomer. The interesting collection of photographs to which I refer included very many remarkable works, taken in most instances by clever provincial photographers. Among those who made excellent contributions were MM. Letellier at Caccia, of Havre; Miesement, of Blois; Blondel, of Lille; Odinet, of Nancy. Besides pictures of monuments, &c., there was also a fine collection of micro-photographs of the plant and insect world contributed by M. Albert Marguery, of Rouen, which was very much admired.

M. Boivin sends me an important communication upon the subject of preliminary films to be employed in the preparation of dry plates. Among the advantages possessed by these films, according to M. Boivin, is the fact that by their use operators may dispense with the most troublesome manipulations connected with the polishing and cleaning of glass plates. The film prevents, in a word, the image formed upon the plate from coming into contact with any injurious substances that may be upon the surface of the glass. Moreover, such a film ensures the adherence of the collodion to the plate, and prevents any air-bubbles or rising of the collodion film. Of all the formulæ which have been recommended for the composition of preliminary films, M. Boivin considers that only very dilute aqueous solutions, and those containing rubber dissolved in benzole, are capable of practical employment. But he hesitates to say which is the better kind. Each has its advantages and its defects. Nevertheless, my friend assures me that rubber is indispensable when resort is had to alkaline development; on the other hand, albumen is to be preferred for acid development.

In general, the operation of acid development is an easier one to accomplish upon an albumenized plate than upon one coated with rubber solution. Of this one can easily convince oneself by covering the two halves of a plate with films of a different nature. Here are the formulæ which M. Boivin has adopted for securing both films of rubber and albumen. In preparing the latter he takes of—

Albumen	...	30 cubic centimetres
Water	...	20 "
Acetic acid	...	1 cubic centimetre.

The acidulated water is poured into the albumen by degrees, and slowly agitating the mixture the while, with a glass rod; then two hundred cubic centimetre further of water are added, and, finally, the whole is allowed to rest for some hours. The liquid is afterward

decanted, the clear part being further filtered through a sponge or bit of fine muslin, and then through paper, when it will be found to be of a most liquid character. The albumen solution treated in this manner may be preserved for a long time; the glass plates are covered with it as in the ordinary way. A glass may be used to aid in the coating, care being, of course, taken to prevent the formation of air-bubbles. As soon as the film has dried completely, the plate is put away with others in a grooved box ready for use at any time. If the albumen is employed in a concentrated condition it will give rise to syrupy streaks over the surface of the plate; it is for this reason that M. Boivin recommends a very dilute solution. As to the rubber varnish, M. Boivin assures me that the best preparation is as follows:—

India-rubber	...	0.2 to 3 decigrammes
Pure benzole	...	100 cub. cents.

The solution is allowed to remain for a few days in a warm locality, and is then filtered through paper. To facilitate dissolution of the rubber, it may be moistened first with chloroform or ether some hours before plunging it into the benzole. The pear-shaped masses of rubber, to be purchased of druggists, is the material that should be used; that in sheets or in tubes will not dissolve. The benzole should be rectified, and exempt from all fatty matter. When the film of rubber has been applied to the surface of the glass plate it should be dried at a good heat; the sooner it dries the less liable is it to crack, but this defect is not to be avoided if the rubber solution is a strong one. M. Boivin recommends the addition of a few centigrammes of gayac resin to the solution. If the latter becomes turbid, it may at any time be clarified with a little fused chloride of calcium, which absorbs the water that is the cause of turbidity; the chloride of calcium will afterwards remain behind upon the filter, being insoluble in benzole.

M. Boivin has sent me an exquisite picture obtained by means of a dry plate prepared on a very simple method, of which he has promised me the description in an early letter; I need hardly say that I shall hasten to communicate the details to the readers of the PHOTOGRAPHIC NEWS.

ERNEST LACAN.

DR. LIESEGANG ON EMULSION NEGATIVES WITHOUT GLASS.*

THE important progress which has been made of late in emulsion processes goes hand in hand with M. Warnerke's sensitive paper films. Of the latter process we have already placed details before our readers. The emulsion is the same as that ordinarily used upon glass plates, but some not unimportant improvements have been made in the material by the use of papyroxyl. Instead of the chalk paper previously used by Warnerke, a strongly-sized paper is substituted as basis for the collodion; for this reason the film negative will not have both sides glazed as formerly, but one will be matt, a detail, however, which will have no influence upon the negative itself.

The paper, as our readers are aware, is alternately covered with rubber solution and collodion several times, and finally coated with bromide of silver, collodion, or emulsion. This sensitized paper is cut to the proper size to go in the dark slide, and pieces are laid upon one another, each with a sheet of orange paper between, and the whole packet enveloped in tin-foil, so as to keep good for some time.

Practical arrangements for changing sensitized paper out of doors, without a dark tent, were invented twenty years ago; their light metal frames with card-board back, upon which the paper was fastened, was one of these arrangements. Over the frame was slipped a cardboard envelope, and the whole put into the dark slide, which was provided with a slit in the side. The dark slide was adjusted, the cardboard envelope drawn out, the lens was uncapped, the envelope again pushed into the slit, and the time of expo-

sure noted, &c. As the frames were light and unbreakable, and required no care in packing, like glass plates, a large number of them, filled with sensitive paper, could be taken about by a photographer. Other, and perhaps better, arrangements could no doubt be suggested. The old arrangement of the Sutton panoramic camera, which had two rollers for unrolling and rolling up of the paper as exposed, would answer; at any rate, I myself have for the past fifteen years employed the system with waxed paper, and found it exceedingly convenient. If there is a dark room handy, the first of the sheets in the tin-foil case is torn off, and, this film having been put away, the case is replaced in the dark slide, taking care that the spring of the latter is not too strong, and does not act so as to bend the packets. The films, as exposed, are put away between yellow paper. Those who prefer to expose the sensitized paper through a glass plate must alter their camera after focussing to the breadth of the plate, so that their picture may be rendered perfectly sharp.

The time of exposure depends, of course, upon the nature of the emulsion that you employ. This material may be produced of a very sensitive nature, but then its development is more difficult; for this reason, it is well at present to employ an emulsion of no very great sensitiveness, which may be developed with certainty. In a good light, to take a landscape view with a rectilinear lens, and full aperture, some twenty to thirty seconds are necessary, and you do well to give rather more, than less, exposure, as a plate which has been over-exposed can be treated successfully with a modified developer, but not so one that has been under-exposed.

The collodion film, whether exposed or un-exposed, must be handled with extreme care and with clean fingers, for a hot or dirty hand leaves marks behind it. Before development, a pin is put under the film to disengage a corner, and then the whole sheet may be pulled off with forefinger and thumb, leaving the yellow paper underneath uninjured. Then upon a glass plate, the same size as the film, you put the latter, having previously moistened the glass with water; you press down the film with filter paper, and so make it lie perfectly smooth and even.

The film is now covered with a mixture of—

Benzole	1 part
Alcohol	10 parts

This is allowed to remain upon the collodion for a couple of minutes in order to soften it, and to prevent the india-rubber from forming spots or patches.

After the film has been exposed and brought back to the laboratory, the development may be conducted in various ways; that is to say, Colonel Stuart Wortley's strong alkaline developer may be employed, a weak alkaline solution, iron, or acid pyrogallol solution and silver.

The strong alkaline developer according to Stuart Wortley's formula is as follows:—

P.—Pyrogallol acid	10 grammes
Alcohol	50 "
A.—Carbonate of ammonia	10 "
Distilled water	80 "

In this case the ammonia is pounded in a mortar, and mixed with the warm water.

B.—Bromide of potassium	10 grammes
Water	160 "

Of these solutions, there is mixed in a glass measure:—

P.	1 gramme
A.	12 grammes
B.	1 gramme

The film is first rinsed with water until it is no longer greasy, and then this mixture is poured upon it. The image at once appears, but when necessary, half as much again of P, A, and B is added. For larger plates, of course, a larger quantity of mixture must be taken. Should the image appear immediately, it is a proof that the film has been too long exposed, and then another gramme of B must be added. Little glass measures are exceedingly useful in undertaking alkaline development.

as in this way one easily accustoms oneself to work with particular quantities.

The weak alkaline developer differs in some degree from that which we have just mentioned, and it should be used for treating the more sensitive films:—

A.—Carbonate of soda ...	10 grammes
Bromide of potassium ...	10 "
Water ...	200 "

Or, instead of the bromide of potassium, half as much bromide of ammonium may be employed.

P.—Pyrogallie acid ...	10 grammes
Alcohol ...	80 "

In applying this developer, you add to twenty-four grammes of water one gramme of P, mix well together, and pour it over the film. The image then appears in all its details. Upon this, the liquid is poured back into the measure, a few drops of it are added, and the image therewith intensified. Or, if preferred, you may pour A over the film first of all, and then add a few drops of P, and, after a few minutes, one or two drops more, when the image increases in intensity.

The iron developer is managed by preparing, in the first place, two solutions; they are:—

A.—Boiled water ...	64 grammes
Citric acid ...	1 "
Nitrate of silver ...	2 "
Copper vitriol (sulphate of copper) ...	8 "

The copper salt is dissolved by itself, and then the silver and acid, having been likewise dissolved, are added. If prepared with boiled water, the developer will hold good a long time.

B.—Sulphate of iron ...	3 grammes
Glacial acetic acid ...	3 "
Water ...	100 "
Or	
Sulphate of iron ...	5 grammes
Water ...	100 "
Methylated spirit ...	5 "

The film is first moistened with water, and then covered with A; this is then poured back into the developing glass, and then a few drops of B are added. The mixture is applied again and again, until all the details come out.

The acid, pyrogallie, and silver developer is undertaken also with two solutions made up as follows:—

A.—Boiled water ...	64 grammes
Citric acid ...	1 gramme
Nitrate of silver ...	2 grammes
Copper vitriol ...	8 "

The copper salt in this case is also dissolved separately.

P.—Pyrogallie acid ...	10 grammes
Alcohol ...	80 "

One gramme of P is put into the glass measure, and twelve grammes of water added to it, and the mixture is then applied to the film, until all the details of the image are developed. Then the solution is poured back into the glass, and a few drops of A are added. With this the negative may be properly intensified. You may proceed also in the reverse order by pouring some of A solution over the film first, and then adding some drops of P.

The fixing of the film is undertaken in the usual manner, either with a two per cent. solution of cyanide of potassium, or an eight per cent. solution of hyposulphite of soda. The process of intensifying may be resumed after fixing, if necessary, as in the case of ordinary wet collodion plates. The film may be intensified by means of Col. Stuart Wortley's process, the following three solutions being made use of:—

C.—Citric acid ...	1 gramme
Water ...	120 grammes
S.—Nitrate of silver ...	3 grammes
Nitric acid... ..	1 gramme
Water ...	100 grammes
P.—Pyrogallie acid ...	10 grammes
Alcohol ...	80 "

A sufficient quantity of C is poured several times over the well washed image, and then for every six parts of C there is added one part of S and P. This mixture will intensify with considerable rapidity, but it is necessary to wash well subsequently, to remove every trace of pyrogallie acid. The film after development may be allowed to remain and dry in contact with the glass upon which it has been developed; or it may be removed and dried between sheets of blotting-paper. You may also, as M. Warnerke has shown allow the film during development to remain upon the paper. To do this the edges of the paper are bent so as to form a tray, and the film is developed in the same manner as if it were upon glass. Before removal from the paper, the film must be perfectly dry, so that the needle may be pierced into it, and in this manner stripped from the paper.

Applied to the glass the varnishing is necessary, if the film has been much intensified. The varnish employed should be of that kind which dries up transparent without being warmed, and for this reason a benzole or chloroform varnish is to be preferred, as also a spirit varnish, which dries up with a smooth surface.

These paper emulsion negatives are scarcely to be distinguished, when finished, from collodion plates, and the copies furnished are vigorous and brilliant. Before printing, the film is made to adhere firmly to a glass plate by the aid of a little water and an india-rubber squeegee. That the films may be printed as well from one side as from another is simply a matter of course. This is a great advantage to the photographer, and one that is especially useful to him if he desires to produce carbon prints by single transfer, or to utilise the Lichtdruck process. Other advantages of the process are obviously the circumstances that, during the preparation and exposure of the film, no glass plates are necessary, while the films can be preserved afterwards with much greater facility. An artistic illustration prepared by the process will appear in the *Archiv* so soon as the weather will permit of its execution.

Instead of emulsion collodion, bromide of silver gelatine may be employed for coating paper. This gelatine has most extraordinary sensitiveness, equal to that of wet plates, and it may therefore be applicable to the taking of portraits in the studio. It is, however, very desirable that photographers should possess a more familiar acquaintance with alkaline development, for it can scarcely be said that the knowledge of its action and of its manipulations are as yet very wide-spread. In all dry processes, but particularly in the case of emulsion films, alkaline development is very valuable, as, by its means, a much shorter exposure may be given than is the case when an acid developer is employed.

A ST. LOUIS PHOTOGRAPHIC STUDIO.

[A CURIOUS element in American journalism, which is at times not a little surprising to the reticent Englishman, is the extent to which they deal with personal matters, in which our American cousins are manifestly deeply interested. Possibly a similar interest might prevail on this side of the water if it were considered decorous either to express it or gratify it. Here is a minute account of a studio in St. Louis under the management of a lady. Mr. J. H. Fitzgibbon, the editor of the recently-established excellent magazine, the *St. Louis Practical Photographer*, having surrendered his portrait practice, the duty is undertaken by his wife, and a St. Louis journal has the following account of a visit to the New Parlour Gallery of Mrs. J. H. Fitzgibbon.]

In all ages of the world the fine arts have been most highly appreciated and honoured among the most enlightened and intelligent nations. From this it is easy, and only just, to infer that wherever a love for the beautiful is found to exist among a people, there will be found education and refinement in a corresponding degree. Arts may be divided—first, into the useful and mechanical; second, into the polite, liberal, and fine. The branch of which we are now treating may be considered as a growth or offspring

belonging to painting, which is recognized as holding the next rank to music and poetry among the fine arts.

These reflections occurred to our mind while making a personal inspection of the various departments of the superb and most elegant New Parlour Photograph and Art Gallery of Mrs. Fitzgibbon. The premises occupied are most advantageously situated, being located at No. 415, Franklin Avenue, are amply large and spacious, no house of the kind, perhaps, in St. Louis possessing more favourable facilities for the conduct of a business of this character. The studio, or operating room, is well supplied with light from all sides, and has been recently fitted up in the latest and most approved plan. These facilities enable sittings to be made at any and all times, no matter what the state or condition of the weather may be. The picture and portrait gallery is fitted up with much taste and elegance, containing a large selection of pictures finished in water, oil, pastel, crayon, Indian ink, and other styles, among which may be found those of some of our most prominent citizens and also of our ladies, high in station and noted for their beauty and refinement. These fac-similes of nature are such truthful representations of their original counterparts that the observer is almost inclined to believe he is in the presence of their actual selves. In this art both Mr. and Mrs. Fitzgibbon have achieved a splendid reputation, and are noted for their faithful pictures. The especial characteristics of their style are, a marvellous freedom and boldness of touch, a wonderful freshness of colour, and a truth of character which bears the most striking individuality and fidelity to nature. Mrs. F. especially excels in the treatment of her visitors in securing an easy pose, in getting a natural expression, and in throwing just the right light, counteracted and set off by the proper amount of shade, upon this or that texture.

Mr. F. is one of the seven oldest photographers in the United States, having begun its practice two years after its discovery, in 1839, which gives him a practical experience of thirty-six years—thirty-one years of which time he has carried on the business in St. Louis. This long experience is known not only to the people of St. Louis, but all over the country, and to-day he is recognized throughout the United States as one of the fathers of photography. Mr. F. publishes a monthly magazine called the *Practical Photographer*, which is one of the only three journals of the kind published in the United States. This journal is very handsome, scientific, and illustrated, and almost indispensable to the progressive photographer. It is devoted to the elevation and improvement of the photographic art, and is kept fully up with, and often in advance of, the times, and is undoubtedly one of the best advertising mediums in the country.

Mr. Fitzgibbon is also permanent secretary of the National Photographic Association of the United States, which is no small testimony of the high regard in which he is held by his brotherhood.

Mr. Fitzgibbon, while he gives his general supervision to all the affairs connected with his elegant gallery, finds himself too much engaged on the *Practical Photographer* to personally attend to each of the many thousands who patronize the establishment, and has very judiciously turned over the management of the gallery to his most estimable lady, Mrs. Fitzgibbon, whose name is familiar to hundreds of our most fashionable and wealthy ladies.

We cannot close this sketch without advising our readers, when in want of an artistic painting or a life-like photograph, to call upon Mr. and Mrs. Fitzgibbon, at No. 415, Franklin Avenue, who are eminent in their profession and reliable in their work, and on all occasions study to please their patrons.

Personally, Mr. Fitzgibbon is an affable and courteous gentleman, while his excellent lady is ever agreeable, and uses every means in her power to make her visitors feel easy and at home.

ENAMEL OR CERAMIC PHOTOGRAPHS.

BY ALEXANDER L. HENDERSON.

[The following is the specification of an enamel process patented last year. We must leave to our readers to ascertain how far a practical process is described, or how far such principle as is apparent differs from that published many years ago by Temie de Motay.]

This invention has for its object the production of photographs in vitrifiable pigments, which may be burnt in upon enamel tablets, glass, porcelain, or metal, the colour of the surface being either white, black, or other colours.

In carrying my invention into effect, I produce first of all either a negative photograph or a transparency of the subject to be vitrified, according to whether the surface upon which the picture is to be placed, and which will hereinafter be termed the enamel, be light or dark in colour. If the enamel be white I treat the transparency with iodides, bromides, or fluorides, such as those of lead, platinum, iridium, manganese, cobalt, titanium, cadmium, mercury, antimony, copper, magnesium, iron, and silver, by floating or immersion. These iodides are combined with mordants, such as bichloride of tin, or chlorides of any kind, sulphantimoniate of sodium, and alkaline or other sulphates with mordants and silicates, which mordants are applied previously, simultaneously, or subsequently to the treatment of the transparency with iodides or bromides; should the intensity of the picture be too great it may be reduced by nitre or hydrochloric acid, or a mixture of both, or by any solvent of the iodides of the metal, or of the metal itself, of which the image is composed. The picture may now, if preferred, be submitted to the action of silicates, such as those of sodium or potassium, the effect of which is to produce the deposited metal as a silicate, which requires no fluxing at the subsequent stage, this being a flux in itself; after which it is transferred to the enamel, which is then fired so as to vitrify the silicate, although the conversion may be effected after its being transferred.

The picture need not necessarily be transferred from one material to another, but may be taken direct upon the enamel. It may then either be left as it is, or may be treated with fluoric acid, by which an intaglio is produced. This may be used as an engraved plate for printing, or may be filled up with enamel colour of any desired tint, and again fired.

If it be not desirable to convert the image into a silicate, or if by accident this conversion has been imperfect, the picture may be fluxed by any of the well-known methods of doing so. I prefer, however, the use of an emulsion, in which the solid matter is borate of lead formed by mixing together acetate of lead and bichloride of soda in their equivalent or combining proportions, the vehicle in which it is suspended being collodion, oil of spike, fat oil, or similar media. This is applied in the way well known to all enamellers.

If the enamel be black or dark, I employ a negative instead of a transparency; but in this case, as the resulting picture must be light in various grades of tone, it must be heated with the iodides or bromides of such metals as will produce a light image, such as those of tin, antimony, arsenic, or any metal that yields a light deposit. The picture thus formed is treated in the same manner as already described.

The proportions required connected with any of the operations depend upon the length of time the image is subjected to receive action, as well upon the tone or colour desired.

As an example of an average working I take of—

Bichloride of platinum, or its compounds	5 parts
Bichloride of tin, or its compounds	80 "
Iodine	to saturation
Acid, such as hydrochloric	900 "
Silicate of potash	30 "
Acetate of lead	40 "
Water	3,000 "

What I claim as novel in this invention is,—

First. The use of bromides and iodides separately or conjointly, used either with or without chlorides and mordants for the production of photographic enamels.

Secondly. The use of these bromides, iodides, and chlorides in conjunction with silicates, as described.

Thirdly. The dissolving away of the vitrified image by means of fluoric acid, and utilizing the intaglio thus obtained either for printing from, or for the production of another image composed of the same or a different material, as described.

as in this way one easily accustoms oneself to work with particular quantities.

The weak alkaline developer differs in some degree from that which we have just mentioned, and it should be used for treating the more sensitive films:—

A.—Carbonate of soda	...	10 grammes
Bromide of potassium	...	10 "
Water	...	200 "

Or, instead of the bromide of potassium, half as much bromide of ammonium may be employed.

P.—Pyrogalllic acid	...	10 grammes
Alcohol	...	80 "

In applying this developer, you add to twenty-four grammes of water one gramme of P, mix well together, and pour it over the film. The image then appears in all its details. Upon this, the liquid is poured back into the measure, a few drops of it are added, and the image therewith intensified. Or, if preferred, you may pour A over the film first of all, and then add a few drops of P, and, after a few minutes, one or two drops more, when the image increases in intensity.

The iron developer is managed by preparing, in the first place, two solutions; they are:—

A.—Boiled water	...	64 grammes
Citric acid	...	1 "
Nitrate of silver	...	2 "
Copper vitriol (sulphate of copper)	...	8 "

The copper salt is dissolved by itself, and then the silver and acid, having been likewise dissolved, are added. If prepared with boiled water, the developer will hold good a long time.

B.—Sulphate of iron	...	3 grammes
Glacial acetic acid	...	3 "
Water	...	100 "

Or

Sulphate of iron	...	5 grammes
Water	...	100 "
Methylated spirit	...	5 "

The film is first moistened with water, and then covered with A; this is then poured back into the developing glass, and then a few drops of B are added. The mixture is applied again and again, until all the details come out.

The acid, pyrogalllic, and silver developer is undertaken also with two solutions made up as follows:—

A.—Boiled water	...	64 grammes
Citric acid	...	1 gramme
Nitrate of silver	...	2 grammes
Copper vitriol	...	8 "

The copper salt in this case is also dissolved separately.

P.—Pyrogalllic acid	...	10 grammes
Alcohol	...	80 "

One gramme of P is put into the glass measure, and twelve grammes of water added to it, and the mixture is then applied to the film, until all the details of the image are developed. Then the solution is poured back into the glass, and a few drops of A are added. With this the negative may be properly intensified. You may proceed also in the reverse order by pouring some of A solution over the film first, and then adding some drops of P.

The fixing of the film is undertaken in the usual manner, either with a two per cent. solution of cyanide of potassium, or an eight per cent. solution of hyposulphite of soda. The process of intensifying may be resumed after fixing, if necessary, as in the case of ordinary wet collodion plates. The film may be intensified by means of Col. Stuart Wortley's process, the following three solutions being made use of:—

C.—Citric acid	...	1 gramme
Water	...	120 grammes
S.—Nitrate of silver	...	3 grammes
Nitric acid	...	1 gramme
Water	...	100 grammes
P.—Pyrogalllic acid	...	10 grammes
Alcohol	...	80 "

A sufficient quantity of C is poured several times over the well washed image, and then for every six parts of C there is added one part of S and P. This mixture will intensify with considerable rapidity, but it is necessary to wash well subsequently, to remove every trace of pyrogalllic acid. The film after development may be allowed to remain and dry in contact with the glass upon which it has been developed; or it may be removed and dried between sheets of blotting-paper. You may also, as M. Warnerke has shown allow the film during development to remain upon the paper. To do this the edges of the paper are bent so as to form a tray, and the film is developed in the same manner as if it were upon glass. Before removal from the paper, the film must be perfectly dry, so that the needle may be pierced into it, and in this manner stripped from the paper.

Applied to the glass the varnishing is necessary, if the film has been much intensified. The varnish employed should be of that kind which dries up transparent without being warmed, and for this reason a benzole or chloroform varnish is to be preferred, as also a spirit varnish, which dries up with a smooth surface.

These paper emulsion negatives are scarcely to be distinguished, when finished, from collodion plates, and the copies furnished are vigorous and brilliant. Before printing, the film is made to adhere firmly to a glass plate by the aid of a little water and an india-rubber squeegee. That the films may be printed as well from one side as from another is simply a matter of course. This is a great advantage to the photographer, and one that is especially useful to him if he desires to produce carbon prints by single transfer, or to utilise the Lichtdruck process. Other advantages of the process are obviously the circumstance that, during the preparation and exposure of the film, no glass plates are necessary, while the films can be preserved afterwards with much greater facility. An artistic illustration prepared by the process will appear in the *Archiv* so soon as the weather will permit of its execution.

Instead of emulsion collodion, bromide of silver gelatine may be employed for coating paper. This gelatine has most extraordinary sensitiveness, equal to that of wet plates, and it may therefore be applicable to the taking of portraits in the studio. It is, however, very desirable that photographers should possess a more familiar acquaintance with alkaline development, for it can scarcely be said that the knowledge of its action and of its manipulations are as yet very wide-spread. In all dry processes, but particularly in the case of emulsion films, alkaline development is very valuable, as, by its means, a much shorter exposure may be given than is the case when an acid developer is employed.

A ST. LOUIS PHOTOGRAPHIC STUDIO.

[A CURIOUS element in American journalism, which is at times not a little surprising to the reticent Englishman, is the extent to which they deal with personal matters, in which our American cousins are manifestly deeply interested. Possibly a similar interest might prevail on this side of the water if it were considered decorous either to express it or gratify it. Here is a minute account of a studio in St. Louis under the management of a lady. Mr. J. H. Fitzgibbon, the editor of the recently-established excellent magazine, the *St. Louis Practical Photographer*, having surrendered his portrait practice, the duty is undertaken by his wife, and a St. Louis journal has the following account of a visit to the New Parlour Gallery of Mrs. J. H. Fitzgibbon.]

In all ages of the world the fine arts have been most highly appreciated and honoured among the most enlightened and intelligent nations. From this it is easy, and only just, to infer that wherever a love for the beautiful is found to exist among a people, there will be found education and refinement in a corresponding degree. Arts may be divided—first, into the useful and mechanical; second, into the polite, liberal, and fine. The branch of which we are now treating may be considered as a growth or offspring

belonging to painting, which is recognized as holding the next rank to music and poetry among the fine arts.

These reflections occurred to our mind while making a personal inspection of the various departments of the superb and most elegant New Parlour Photograph and Art Gallery of Mrs. Fitzgibbon. The premises occupied are most advantageously situated, being located at No. 415, Franklin Avenue, are amply large and spacious, no house of the kind, perhaps, in St. Louis possessing more favourable facilities for the conduct of a business of this character. The studio, or operating room, is well supplied with light from all sides, and has been recently fitted up in the latest and most approved plan. These facilities enable sittings to be made at any and all times, no matter what the state or condition of the weather may be. The picture and portrait gallery is fitted up with much taste and elegance, containing a large selection of pictures finished in water, oil, pastel, crayon, Indian ink, and other styles, among which may be found those of some of our most prominent citizens, and also of our ladies, high in station and noted for their beauty and refinement. These fac-similes of nature are such truthful representations of their original counterparts that the observer is almost inclined to believe he is in the presence of their actual selves. In this art both Mr. and Mrs. Fitzgibbon have achieved a splendid reputation, and are noted for their faithful pictures. The especial characteristics of their style are, a marvellous freedom and boldness of touch, a wonderful freshness of colour, and a truth of character which bears the most striking individuality and fidelity to nature. Mrs. F. especially excels in the treatment of her visitors in securing an easy pose, in getting a natural expression, and in throwing just the right light, counteracted and set off by the proper amount of shade, upon this or that texture.

Mr. F. is one of the seven oldest photographers in the United States, having begun its practice two years after its discovery, in 1839, which gives him a practical experience of thirty-six years—thirty-one years of which time he has carried on the business in St. Louis. This long experience is known not only to the people of St. Louis, but all over the country, and to-day he is recognized throughout the United States as one of the fathers of photography. Mr. F. publishes a monthly magazine called the *Practical Photographer*, which is one of the only three journals of the kind published in the United States. This journal is very handsome, scientific, and illustrated, and almost indispensable to the progressive photographer. It is devoted to the elevation and improvement of the photographic art, and is kept fully up with, and often in advance of, the times, and is undoubtedly one of the best advertising mediums in the country.

Mr. Fitzgibbon is also permanent secretary of the National Photographic Association of the United States, which is no small testimony of the high regard in which he is held by his brotherhood.

Mr. Fitzgibbon, while he gives his general supervision to all the affairs connected with his elegant gallery, finds himself too much engaged on the *Practical Photographer* to personally attend to each of the many thousands who patronize the establishment, and has very judiciously turned over the management of the gallery to his most estimable lady, Mrs. Fitzgibbon, whose name is familiar to hundreds of our most fashionable and wealthy ladies.

We cannot close this sketch without advising our readers, when in want of an artistic painting or a life-like photograph, to call upon Mr. and Mrs. Fitzgibbon, at No. 415, Franklin Avenue, who are eminent in their profession and reliable in their work, and on all occasions study to please their patrons.

Personally, Mr. Fitzgibbon is an affable and courteous gentleman, while his excellent lady is ever agreeable, and uses every means in her power to make her visitors feel easy and at home.

ENAMEL OR CERAMIC PHOTOGRAPHS.

BY ALEXANDER L. HENDERSON.

[The following is the specification of an enamel process patented last year. We must leave to our readers to ascertain how far a practical process is described, or how far such principle as is apparent differs from that published many years ago by Temie du Motay.]

This invention has for its object the production of photographs in vitrifiable pigments, which may be burnt in upon enamel tablets, glass, porcelain, or metal, the colour of the surface being either white, black, or other colour.

In carrying my invention into effect, I produce first of all either a negative photograph or a transparency of the subject to be vitrified, according to whether the surface upon which the picture is to be placed, and which will hereinafter be termed the enamel, be light or dark in colour. If the enamel be white I treat the transparency with iodides, bromides, or fluorides, such as those of lead, platinum, iridium, manganese, cobalt, titanium, cadmium, mercury, antimony, copper, magnesium, iron, and silver, by floating or immersion. These iodides are combined with mordants, such as bichloride of tin, or chlorides of any kind, sulphantimoniate of sodium, and alkaline or other sulphates with mordants and silicates, which mordants are applied previously, simultaneously, or subsequently to the treatment of the transparency with iodides or bromides; should the intensity of the picture be too great it may be reduced by nitre or hydrochloric acid, or a mixture of both, or by any solvent of the iodides of the metal, or of the metal itself, of which the image is composed. The picture may now, if preferred, be submitted to the action of silicates, such as those of sodium or potassium, the effect of which is to produce the deposited metal as a silicate, which requires no fluxing at the subsequent stage, this being a flux in itself, after which it is transferred to the enamel, which is then fired so as to vitrify the silicate, although the conversion may be effected after its being transferred.

The picture need not necessarily be transferred from one material to another, but may be taken direct upon the enamel. It may then either be left as it is, or may be treated with fluoric acid, by which an intaglio is produced. This may be used as an engraved plate for printing, or may be filled up with enamel colour of any desired tint, and again fired.

If it be not desirable to convert the image into a silicate, or if by accident this conversion has been imperfect, the picture may be fixed by any of the well-known methods of doing so. I prefer, however, the use of an emulsion, in which the solid matter is borate of lead formed by mixing together acetate of lead and bichloride of soda in their equivalent or combining proportions, the vehicle in which it is suspended being collodion, oil of spike, fat oil, or similar media. This is applied in the way well known to all enamellers.

If the enamel be black or dark, I employ a negative instead of a transparency; but in this case, as the resulting picture must be light in various grades of tone, it must be heated with the iodides or bromides of such metals as will produce a light image, such as those of tin, antimony, arsenic, or any metal that yields a light deposit. The picture thus formed is treated in the same manner as already described.

The proportions required connected with any of the operations depend upon the length of time the image is subjected to receive action, as well upon the tone or colour desired.

As an example of an average working I take of—

Bichloride of platinum, or its compounds	5 parts
Bichloride of tin, or its compounds	30 "
Iodine	to saturation
Acid, such as hydrochloric	500 "
Silicate of potash	30 "
Acetate of lead	40 "
Water	8,000 "

What I claim as novel in this invention is,—

First. The use of bromides and iodides separately or conjointly, used either with or without chlorides and mordants for the production of photographic enamels.

Secondly. The use of these bromides, iodides, and chlorides in conjunction with silicates, as described.

Thirdly. The dissolving away of the vitrified image by means of fluoric acid, and utilizing the intaglio thus obtained either for printing from, or for the production of another image composed of the same or a different material, as described.

SOLAR CAMERA ENLARGEMENTS IN CARBON.

THE use of the solar camera has been for some time past declining in the country: or, perhaps, we might more accurately remark, it has declined, and almost entirely ceased. There are many reasons which will account for this. Primarily, the rarity and uncertainty of direct sunlight, which is a condition of absolute necessity for the successful use of this mode of enlargement. Then, even when sunlight could be secured, the process of enlarging direct on sensitive albumenized paper was so tedious and slow that it almost rendered such a method prohibitory. Where development printing was considered good enough, the solar camera was useful; but, except as a basis for painting or for elaborate retouching, developed prints were rarely satisfactory, often poor in colour, and seriously lacking brilliancy. The very superior prints obtained by printing from an enlarged negative, and the improvements in producing such negatives, have brought this method of securing enlargements into general use, greatly to the advantage of that class of work generally.

We have recently seen, however, some direct prints produced in the solar camera which will go far, we think, to give that instrument a renewed tenure of favour. The prints in question are in carbon, produced direct on sensitized tissue by Dr. Van Monckhoven, and we were indebted for an opportunity of inspecting them to the courtesy of Mr. J. A. Spencer. Our readers know that Dr. Van Monckhoven is the inventor and patentee of an improved solar camera, with a reflector of great power, some of the finest solar camera prints ever seen in this country having been shown by Dr. Van Monckhoven when his new instrument was described. Using this instrument, and ordinary sensitive carbon tissue, he has found that the time required for printing is exceedingly short. The exposure of the specimens we examined had varied from four minutes to ten, and most of them were slightly over-exposed. About six or eight minutes appeared to be the best time. Carbon printers are familiar with the fact that sensitive tissue requires much less exposure than albumenized paper. In our experience we have often found one-third of the exposure sufficient; but judging from the time which would, in our estimate, have been required by albumenized paper, the exposure can scarcely have been more than one-tenth of the time required by silvered paper. If to this be added the possibility of reduction to be obtained by bringing in the aid of the continuing action which takes place in exposed carbon tissue, the exposure may be still more reduced, and possibly very considerably.

If the rapidity were obtained at the sacrifice of any good quality it would not be worthy of consideration; but the

prints in question were not only in every way excellent, but singularly fine; the modelling was unusually perfect, giving a rare softness and solidity to the images not often found in ordinary photographs. Of course much of this is due to the excellence of the original negatives, but it was clear that all the delicacy and detail in the negative had received full justice. When Dr. Van Monckhoven described his apparatus before the Parent Society, he exhibited clichés especially suited to the work, produced from the original negative by means of the collodio-chloride process, and some of the quality of the prints was doubtless due to the rare delicacy of the collodio-chloride image. But the negatives from which the enlarged prints to which we have referred were produced, appear to have been ordinary negatives, some varnished, and some unvarnished; some untouched, and some worked upon. We hope that in the forthcoming Exhibition all our readers may have an opportunity of inspecting similar specimens, as we have reason to hope that Dr. Van Monckhoven will contribute examples.

PRACTICAL EXPERIENCE IN CARBON PRINTING.

ON another page we publish a further very practical letter from Mr. C. Witcomb, of Salisbury. Our readers will remember that, some months ago, Mr. Witcomb, then little more than a tyro in carbon printing, gave a history of his experiences in carbon printing, adding some very valuable practical hints as to the mode in which he had overcome difficulties, and attained a high degree of success; that success. Since then Mr. Witcomb has gone on working the process, proving its capacities through the hottest and, therefore, most trying season of the year. The result is, that he is only still more in love with the process. He finds the method easy and the results exceedingly good. His customers like them, and are willing to pay extra for them. The commercial results are as satisfactory as the artistic. Mr. Witcomb's experience must be singularly interesting to professional portraitists. An example he forwarded to us is exceedingly fine. It is without the exceedingly glossy surface usually given to "chromotypes"; but has simply ivory textured surface given to the tissue by rolling or burnishing without the enamelling aid of plate glass.

Mr. Witcomb raises one or two points of considerable practical importance. The first will probably cause no controversy. It consists in a recommendation to allow the exposed print to remain a little longer soaking in cold water than is usual before commencing development with hot water. This commends itself at once to the judgment, and will probably be accepted without dispute. The second point relates to the strength of the bichromate bath for sensitizing the tissue. The bath recommended in the Autotype Company's Manual contains one ounce of the bichromate salt to thirty ounces of water. This Mr. Witcomb finds not sufficiently strong. The point is one for practical men, and can only be decided by careful observation during extensive experience. In Mr. Swan's early experience, and, we believe, his continued experience, he preferred a pretty strong bath, generally using one part of the bichromate salt in twelve parts by weight of water. A standard strength, which came generally into use when the process began to be practised by photographers, was one in twenty. In our own experiments we have generally used a solution containing one ounce of bichromate in a pint of water, and this we have found answer well. Mr. Witcomb speaks with much confidence of the value of a bath of similar strength, and his opinion is certainly worthy of attention. We strongly commend all our readers to read his letter with attention, and mark the enthusiastic confidence and trust which he has in carbon, as far surpassing silver in simplicity, certainty, and excellence, and also mark that it is the result of experience.

IRREGULAR PHOTOGRAPHIC EXPERIENCES.

MR. JOHN S. GIBON, in recording in our Philadelphia contemporary his labour in photographing in the late Centennial Exhibition, relates some interesting and curious experiences from which many hints may be derived. Here are some extracts:—

It was a matter of great wonderment with many, and experienced photographers were sometimes to be included with "the many," that we could succeed in producing such fine "interiors," irrespective of the masses of people constantly surging about. I am forcibly reminded of something that made a great impression on me at the time, and occurred whilst I was but an apprentice in photography. An old stager in the line of a "viewist" was showing me some gems, representing brooks and cascades, tripping and dashing through masses of well-defined foliage. In my innocence and ignorance I was quizzing him as to how he managed to make his pictures, some parts of which seemed to have had only instantaneous exposures, and others a very full time.

"Why, you young fool!" he replied, "do you not know that if you cannot get such a picture in half a second, the half of an hour will do as well?" So with us, the longer the exposure—with all due deference, of course, to the qualification of our plate—the better.

The columns, adornments, and masses of goods did not move; but the people, happily, passed along, and, but in exceptional instances, individual parties remained so short a time in any one place, that they made no apparent impression upon our plates.

The Centennial Photographic Company spared no expense in procuring the best materials, apparatus, lenses, and what they deemed the highest order of talent, to further their plans. Numbers of operators were congregated together, and I can bear testimony to the general disposition towards exchanging experiences, in preference to any reticence of opinion.

I must give Mr. Kilburn, of New Hampshire, the credit of having injected an idea into my head, that, without him, it would probably have been devoid of. We had been considerably troubled with streaks and curious markings in the "open skies" of some of our landscape negatives. After removing a plate from the silver bath, we had adopted the plan of well draining it, and then rubbing the back perfectly dry with "Jo" paper. Mr. Kilburn proposed to suspend the latter operation, and, simple as the expedient was, it seemed to remedy in a great measure the difficulty. It is astonishing how really valuable these little dodges become.

The Board of Finance had granted permission to a certain passenger railway company the privilege of running cars upon tracks planted most detestably near (photographically speaking) to the principal buildings. These cars—the rails upon which they were run, the sleepers that upheld the latter, and, in fact all the appurtenances to such a railway—gave us a heap of trouble.

As adjuncts to the making up of a foreground they were not a success, and it was difficult to secure the picture of a building when, *ad interim*, the scream of a locomotive's whistle would not be heard, or the clouds of steam escaping from it could not be seen.

I feel entirely confident in the assertion that railway accessories, consisting generally of lines or iron bars, of broken roads, ugly fences, dilapidated platforms, and hastily improvised ticket offices, are not, as a general thing, the happiest accompaniments to a picturesque composition. To get rid of these, then, the only resource was to remove to a long distance from your object, and force more attractive bits into your foregrounds by the use of even six or seven-inch lenses for stereoscopic purposes. My own preference finally induced me to adopt lenses of four-inch focal length as being the most generally serviceable.

In some cases, in order to supply the demand for pictures

of objects of extraordinary interest, we were ordered to make as many as one hundred stereo negatives without change of position. To facilitate this end, we had furnished to us boxes for stereoscopic purposes that carried four tubes upon their fronts. Using eight by ten plates, we could then obtain upon one glass two double negatives, each of them five by eight inches in size. Under such circumstances, however, we were sadly restricted as to much movement of the instrument. In the first place it was entirely necessary to have it scrupulously level. Then, obviously, you could neither swing the back, nor alter the upward or downward position of the lenses.

Again, all of the tubes had to be exactly matched, and I imagine that all will agree with me as to the difficulty in obtaining four objectives all equally perfect and persistently alike.

It will occur to many that we had a good many acres of ground to traverse over, and that some of the buildings represented large fractions of a mile in length. How did we manage the dark room operations will be the next query? In the photographic studio proper there was a good sized apartment, fitted with all the appurtenances of a "dark room." This was for general use, and intended as the centre of operations when our instruments were not removed too far from it. To provide for such emergencies, smaller, although convenient, dens were constructed in the most prominent buildings; and, again, every known moveable description of waggon, closet, or tent brought into use.

The most important of the latter contrivances was drawn around by a horse, and the appearance of the animal, with its burden, became sufficiently well known to claim for its historic pretensions. It was most certainly made the subject for a "poem," but that, like many another good thing, will have to be consigned to oblivion. Furthermore, we had two-wheeled arrangements that you could perambulate about in any direction. Sticking your body, from the waist upwards, in one of these, your nether extremities never failed of eliciting all sorts of remarks from the passers-by. One day, while seeking privacy in one of these travelling boxes, and being industriously engaged in the preparation of a plate, I was most unexpectedly treated to the capsizing of the whole concern. A sudden gust of wind, the precursor of a thunderstorm, swept over the affair and turned it upon me.

You can imagine the effect. The caboose was well supplied with chemicals, and carried a bath capable of coating eleven by fourteen plates. That drenched me from head to heels. The accompaniments of iron developers, pyrogallie intensifiers, and the hodge-podge of other little photographic niceties, all tended to my personal adornment. Half an hour afterwards the appearance of my face and body outrivalled the scars, streaks, or tattooing of any Fiji Indian, and I believe that if I had sought an engagement from Barnum as a specimen of ugliness I should have been at once offered a handsome livelihood.

The dragging around of these photographic vans was no great joke in the hot months, and although we condensed our outfit to useful and necessary things only, we still had a good deal of dead weight to tug after us.

For a day's work we had to be provided with at least three differently sized camera boxes and their appropriate lenses; tall and short tripods, with a step-ladder; baths, developers, collodions, and sometimes water; last, and heaviest of all, boxes of glass.

I have heard all sorts of assertions in regard to the capacities of an operator in the production of view negatives. Take them as they would run, assorted sizes, and with the aid of a competent assistant, I have felt completely tired out and overworked when I have brought in a return of fifty plates for a day's work.

I recall with the utmost reverence the stories that I used to listen to in the earlier days of photographic experiences, of how certain gentlemen, evidently magicians in

our art, were able to attend to the demands of hundreds of customers daily. With me, it has always taken time to make a negative—or, at least, a good one.

MONOCHROMATIC LIGHT IN PHOTO-MICROSCOPY.

BY CAPTAIN ABNEY, R.E., F.R.S.

WHEN using a microscope for photographic purposes, particularly when a high magnifying power is employed, the residual uncorrected achromatism is often very marked, and a photograph of any object is frequently ill-defined, particularly when the exposure requisite for one part is greatly different to that required for another part, since the exposure given to one may be sufficient to cause the lesser actinic rays to have an effect, whilst on the other only the more actinic rays are really utilized.

There is also always a difficulty in obtaining a true focus, many trial plates often being wasted in obtaining it actinic. When monochromatic light is used, however, this last difficulty vanishes, and, of necessity, there is no danger of want of definition from the inequality of exposure. I am not aware that the method now proposed has ever been adopted by photo-microscopists; at all events, I cannot find any published account of it. I therefore trust that, to the readers of the NEWS, it may be novel.

A is a heliostat throwing the sunlight on B, which is a condenser of four feet focus. D is a lens of about twelve inches focus, which takes the place of the collimating lens in any ordinary spectroscopic arrangement. The

Arrangement for Monochromatic Light with the Microscope.

rays of light, after passing through the condenser B, are focussed on the slit C. The lens D is so arranged that it throws the rays parallel on to the prism, E (which may be one formed with carbon disulphide). The rays of light, after being dispersed by the prism, are collected by the lens, F, which should be of varying focus according to the power of the microscopic objective. The spectrum so produced should be focussed on the slide G, containing the subject to be photographed, the camera, H, being in the position shown. Should it be feasible to hold the microscope in a horizontal position, there is no difficulty in this, but where the camera has to be in a vertical position, the mirror attached to the stand must be employed.

The higher the power the shorter should be the focal length of F. With a quarter-inch power, a focal length of 2½ inches will be sufficient. The reason of this varying focal length is that the whole of the subject embraced by the objective should be illuminated approximately by the same coloured light. For the same reason the slit should be rather widely opened—so wide, indeed, that its breadth should be at least equal to the breadth of subject in the field of the objective. This opening on the slit prevents the light from being absolutely pure, but it is sufficiently so to prevent any appreciable change of focus being required for the rays embraced in the small part of the spectrum employed.

A somewhat similar plan for obtaining monochromatic light may be substituted for the above. The sunlight may be thrown directly in the prism by the heliostat, and the rays brought to a focus on the slide by means of a lens. If this plan be adopted the impurity of the spectrum varies according to the focal length of the lens employed, since an image of the sun is formed by such monochromatic rays, and these overlap. Though more complicated, the first plan is considerably preferable where a high power has to be employed. In using this monochromatic light it is essential that the direction of the ray of light employed to illuminate the object should lie in the continuation of the axis of the objective; or, in other words, if the objective were removed it should strike the centre of the sensitive plate. Failures have occurred in my own practice through not taking this precaution.

With wet plates the best rays to employ are the blue immediately following the green in the spectrum; when the object is seen to be illuminated with the violet, the exposure will be found to be unnecessarily prolonged. With dry bromide plates a greenish blue may replace the blue rays. It may be noted that when working visually with the microscope the use of monochromatic light is a source of comfort, many details, which are only indistinctly seen, being rendered much more perfectly. By shifting the collimating lens in a plane at right angles to the general direction of the rays, a ray of any colour that may be required can be caused to illuminate the object; and, for visual observations, this is particularly useful, since some particular colour may be more suitable than another. When photographing opaque objects by the light they reflect, the difficulties increase; but when once they are illuminated by the proper light, cast at a proper angle with the axis of the objective, the employment of dry plates renders feasible what would otherwise be impossible when wet plates are used. The same may be said for the substitution of the lime light, or the electric light, for sunlight. With the two former it is possible to use wet plates when only moderate magnification is required, but when an amplification is required of five hundred diameters, dry plates or sunlight are essential.

A TOUR IN THURINGIA.

BY H. BADEN PRITCHARD.

THE Thüringer Wald, as a fir-clad district of hill and dale is called in Mid-Germany, has been a favourite playground of mine ever since I was a school boy at Martin Luther's "dear old Eisenach." I may not have all the affection for the quaint forest town that the great Reformer evidently felt, but of the charming woodland scenery around I have ever had pleasant reminiscences. There is a wildness and seclusion about Thuringia hardly to be found in other "beauty spots" so near great cities; and, although many travellers may actually come to Eisenach to visit the famous Wartburg, where Martin Luther was confined for some time, and where he translated a large portion of the Bible, these make but a flying visit of it, and are generally off again on their travels in twenty-four hours.

I have not moved out of my comfortable quarters at the "Rautenkranz Hotel," and shall be glad indeed if the rest of my holiday is spent so pleasantly. I do nothing all day but wander about the deep-shadowed pine forests, mounting a breezy peak to get some pleasant view, or looking up from below at some precipitous cliff, yellow and green with lichen and ferns. I have a small camera slung over one shoulder, and a Warnerke roller dark slide over the other, while my tripod constitutes a trusty staff. Inside this roller dark slide is a roll of sensitive tissue sufficient for thirty-five pictures; in my portmanteau at the hotel is another roll of equal dimensions. In my three weeks' holiday, therefore, I shall be able to take seventy pictures, and this, too, without the least trouble or bother. After making an exposure in the camera I have to turn a

roller with one hand, fix two buttons with the other, and behold! within the space of half a minute I am ready to take the next picture. I meet from time to time a sympathizing traveller.

"Ah! you work with dry plates, I see; very convenient, is it not?"

But when I show my light wooden box, and explain that I have sensitized material therein for nearly two score of pictures, the stranger is nonplussed, and would fain take the box in his hand and open it. But Mr. Warnerke has had the precaution to furnish it with lock and key, and, moreover, I will not let it out of my hands. But I show how it works—how the tissue is coiled from one roller to the other, as, bit by bit, it is exposed; and then our German cousin, who at once appreciates the wonders of the instrument, bursts out with such encomiums as, *wunderschön, prachtvoll, ausserordentlich, colossal, &c.*

But, after all, this forest scenery, these green hills and dales, mossy defiles, and grotto-like retreats, do not make very wonderful subjects for the camera, it may be said; or, at any rate, you could get camera-pictures of the same sort, and quite as pretty, nearer home. True; I admit it. But the district of Thuringia is something more than a holiday district. It is hallowed by history, and enhanced by romance. The Landgraves of Thuringia were the old feudal princes of Germany, as their strongholds, like those of the Picts, may be said to have never been invaded. Within a dozen miles of Eisenach you may probably count as many hill-tops that have once been surmounted by trusted burghs, of which many traces still exist; while for legend and fairy tale there is no more prolific district, the Harz mountains not excepted.

My first walk is on the road to Ruhla, a prosperous market town where the famous Ruhla meerschaum pipes are made, of which I am sure many of my readers have heard. At the old-fashioned village of Farnroda I step out of the main route for a moment to take a view of the Wittgenstein. This is a picturesque bit of grey rock, fringed with trees, and I manage to get some old farm-buildings as a foreground. There is a legend connected with this romantic spot which is worth telling. Once upon a time—I believe that is the proper way to begin—there was a castle on those heights, and in it dwelt a knight and his daughter. I need scarcely tell you that the daughter was very beautiful, for that is a matter of course; neither need I say that the knight, her father, was a "crusty old codger," for that, too, goes without saying. In time, a quarrel arose between them on the subject of a suitor, for when the father proposed a certain match, the daughter, it seems, had already set her heart upon a dashing young fellow who used to come to see her every night upon a coal-black charger. Upon this, the father, as was to be expected of him, stormed and fumed, and made use of bad language, of which I believe sounds and s' death formed prominent words, and at last sent out his vassals to waylay and murder the young man. The body of her lover was brought to the young lady, and she, as in duty bound, fainted away and expired on the spot. For a long time afterwards, however, the ghost of the slain rider came riding his coal-black steed to Wittgenstein, until at last, with the aid of the Evil One, the father was enabled to banish him to a mountain opposite. The spirit of the damsel still haunts the Wittgenstein to this very day, and it is not so long ago, we are told, some musicians returning home to Ruhla late one night, stopped opposite the place to give her a serenade. As they were packing up their instruments, a dwarf came upon them suddenly, and presented each with a twig of oak, which most of them, however, had pulled to pieces and thrown away by the time they reached home. One only stuck it in his cap, and he was surprised the next morning, when his wife asked him what that yellow thing was, to find a sprig of burnished gold, with oak leaves and acorns all of the shining metal, pinned to his wideawake.

That is why I stopped to take a picture of the Wittgenstein before going to Ruhla, where I take pictures of its narrow streets and its primitive kurbhaus; for Ruhla is a spa, as well as the seat of the pipe-making trade, although, seemingly, with few visitors. The little brook which runs down the middle of the place, and over which you may jump at a spring, serves to divide the duchies of Saxe-Weimar and Gotha. It does not matter much now, for it is all one "empire;" but time was, and that not ten years ago, when it was of some importance to an inhabitant of Ruhla whether he lived on one side of the stream or the other. Thus a man on the Gotha side could catch nightingales, and hang up their cage outside his door, while his neighbour over the way would be subjected to fine and imprisonment if he did such a thing.

On my way back to Eisenach I find plenty to do for my camera, the castle of Wartburg, upon its lofty pedestal, presenting now and then a magnificent object in the landscape. Then I come to the Princess rock, a steep, fantastic bit of cliff, and this, also, I must get a picture of for the sake of its legend. In this rock there is imprisoned a princess, who only appears in this world once every hundred years, and then, I believe, in the night. She has no end of money and treasure locked up with her, and any one who frees her from the charm or "spell" under which she suffers will secure princess and treasure for himself. This, however, can be done in one way only. When the princess appears she sneezes ten times, and if a man hearing her calls out *Gesundheit!* or "Your health!" after every sneeze, he secures the princess for a bride. The last time she appeared, it is said, that as soon as she began sneezing, a voice from the road once replied, *Gesundheit!* and did so, indeed, nine times running. But when the princess sneezed for a tenth time the voice grew angry, and was heard to say, impatiently, "Oh, go to the deuce with your sneezing!" Whereupon a loud burst of thunder came, and the princess was heard no more.

It is now growing dark, and, as I am a bit nervous, I shall go home.

THE TEXTURE OF NEGATIVES.

Mons. J. GILARD gives, in the *Moniteur de la Photographie*, some interesting details of a microscopic examination of the texture of negatives. He remarks, that a microscopic examination of the sensitive collodion film in its different stages, from the moment when it is plunged into the silver bath until the image is definitely fixed, presents numerous modifications in its molecular texture. These modifications take at first a basic character proper to each reaction, and then assume variations differing among themselves according to the elements placed in presence. They play an important part in photographic manipulations, for there are grounds for supposing that in determining, by means of the microscope, the effects produced in the impression of the sensitized coating, we can discover there the necessary elements for investigations in the case of failures.

The crystals of iodide of silver which are formed on the collodion during its sensitizing in a neutral silver bath vary according as the collodion is old or new. In the first case the surface presents a reticulated appearance, in which may be discovered irregularities or whites; in the second case it is covered with well characterized crystals, uniformly distributed; but in the places where the nitrate of silver has remained in excess, other radiating crystalline systems, like roses, show themselves in spots visible to the naked eye. If the plate has been washed on coming from the bath after sensitizing, no perceptible crystals will then exist. It is manifest, therefore, that different reactions show themselves in collodions more or less old placed in the same silver bath.

The reducing agent, either the sulphate of iron or the pyrogallie acid, causes the blacks and half tones to appear by forming a precipitate on the infinitely small crystals incorporated in the thickness of the sensitized coating. The

same reaction is also made on those which adhere to the surface, but without influencing the coating proper. This excess is kept there by capillary affinity, and constitutes the fog. It is certain that this multitude of crystals is superficial, since the fog may be removed with a wet cotton tuft, provided the coating offers sufficient resistance to bear its contact.

Examining any negative with a magnification of at least 800-1, we remark first in the clear portions, those that are the most diaphanous, crystalline molecules, no larger than the two-hundredth of a millimetre; it is these that form the fog. In the second case, in following gradually a tone of progressive intensity, we see in the thickness itself of the coating a number of small amorphous crystals, which are so much the more numerous in proportion to the darkness of the tone. They form by their agglomeration a felted concretion, impervious to light. Light decomposes the silver salts in a latent manner, the crystals of which dissolve themselves by the action of the reducer.

HELP ONE ANOTHER.

BY THOMAS L. PAVIOUR.

I AM sure it is with great pleasure that I congratulate Mr. Norman May on his subject entitled "Photography in America," which I read with much interest. I feel with him that there should not be such an indifference shown one towards another connected with the art of photography. Yet it is so. There are many who would clap their hands at the fall of a brother, and delight in seeing him come to the dogs. There is not a very great chance of English photographers catching up to the Americans when things go on in that way. If it is possible to help a brother, help him, and not run off to the Patent Office as soon as you have found out some little improvement. In short, if you cannot help him, do not hinder him. There are those retouchers and operators who prefer to hold secret some medium that they may have found out, and would not tell another on any account. But those who do their best, and try to be of some help to others, may receive the following, and give thanks by help in return:—

For Retouching.—To cause a tooth on varnished negatives, take a piece of india-rubber or ink erasure and rub lightly those parts to be retouched, taking care that all bright streaks disappear. There will be found tooth enough for a HH pencil, and may be worked over more than once or twice without destroying the tooth, which is a very great advantage sometimes.

For Enlarging.—Give your enlarged negative just half the exposure you give the transparency (silver), and you cannot fail. For portrait work in winter, a little acetate of morphia (say two grains to each negative) will be found a good thing, to help up the quality of the negative.

The cause of those streaks and flashes which are often seen in negatives, is to be found in the collodionized plate being put into the silver bath too quick. The plate, when ready, should be lowered to the top of the solution, and then firmly, but gently, moved towards the bottom of the bath.

For Working-up Autotypes and Touching Chromotypes.—Ivory-black and crimson lake I have found (only don't tell the Autotype Company) the best, as you can shade with the ivory-black to suit the tone of your picture. For autotype, use water; for chromotypes, use gelatine 1 ounce, water enough to allow it to swell for two or three hours, when it must be boiled until quite dissolved in four ounces of water, and not allowed to get quite cold while using.

Correspondence.

DESIGN IN PHOTOGRAPHY.

DEAR SIR,—It must be evident to all your readers that the beauties cannot be estimated nor the defects detected

in any thing of the formation of which the observer has not theoretical and practical knowledge. This is most especially the case with all works of art, without exception; therefore, it necessarily follows that without artistic education, the photographer is not able to judge of his own works: the gross blunders constantly to be seen, even in the most simple subjects, produced by ignorant operators, sufficiently confirms this.

With a mind so benighted as not to be able to discriminate between the grotesque attitudes of a dancing bear and dignity of a god, any attempt at grace either in attitude or expression must prove a failure. And what marks the difference? Simply the combination, proportion, and position of the lines forming the design. Allowing, then, the necessity of such knowledge, it seems somewhat curious that it is not more generally taught in schools as an essential part of youthful education, instead of being reckoned, as it now is, only an accomplishment, especially as it is as easily acquired as writing, and would materially aid the pupil in forming a good legible hand, instead of the horrible scrawls which are so frequently seen, bearing no traceable resemblance to the copies they have had placed before them. As many may have the will and the time to study, and yet may not be able to leave their place of business, or procure a master, I will point out a course, and make a few remarks by aid of which, with perseverance and well selected copies, any one of moderate capacity may become highly proficient in the art of design.

To begin with the beginning, a line is considered to be a continuous series of points; they may be termed straight, curved, or irregular; their position denominates them an upright or vertical, oblique, horizontal, angular, circular, oval, or spiral; the three latter may more properly be said to be geometrical forms. As a beginner must necessarily make many attempts before he can acquire sufficient facility of hand to produce any design worthy of being preserved, the materials with which he begins his studies should be of an inexpensive nature, as capable of being repeatedly used. The great artist, Giotto, when but a shepherd's boy, used to sketch portraits of his sheep upon the adjacent rocks. A board painted over with black flattening, and a piece of common chalk, or a sheet of glass ground on one side, using a blacklead pencil as a marker, are well fitted for this contrivance. Tracings can be easily made, and then reduced by the camera for magic lantern slides.

As drawing requires a greater freedom of the action of the wrist than writing, the back part of the fingers should be towards the paper or other materials on which the design is being executed; and it is best not to touch it with the fingers at all. A maul-stick is used by artists to support the weight of the arm; at the present stage it is not required, and better not used. Having an ensel, the pupil can either sit or stand while at work.

Fearing to take up too much of your space, I will with your leave continue this subject in my next paper.—I am, dear sir, yours truly,

JAMES MARTIN.

5, Clarence Place, Ilfracombe.

TOUGHENED GLASS.

DEAR SIR,—In your issue of the 24th I notice some remarks regarding the use of toughened glass for photographic purposes, and now have pleasure in handing you some particles which will no doubt prove of interest to your readers.

I may further add that toughened glass is decidedly much cheaper than ordinary glass if strength is anything to go by. As an example, supposing a party is in the habit of using 26-ounce sheet glass, which costs at the manufacturer's 4d. per foot; if he substitutes 15-ounce toughened sheet glass, which costs 2½d. per foot, he will save over 45 per cent., and still have the same or greater strength than he has in 26-ounce.

Our works are now in full work, and the glass is giving the greatest satisfaction, if we may judge from our influx of

orders. The thinnest toughened glass we manufacture is tested, before going out, with a leaden bullet, so that it would resist the greatest storm of hailstones that ever was.—
Yours obediently,
W. J. MASON, Managing Director.
79, Corporation Street, Manchester.

As the works of the company are situated in Stockport, no doubt a few further particulars will prove of interest to our readers. The character of toughened glass on its first introduction into the market was very much exaggerated. From the various erroneous accounts, most people are under the impression it is unbreakable. This is not the case; as its name implies, it is ordinary glass submitted to a process by which it is made tough, and becomes thereby some ten times stronger. For example, a weight of three ounces dropped from a foot high on to a piece of window glass of ordinary thickness will break it, whilst the same thickness of glass toughened will not break by dropping the same weight upon it from the height of twelve feet. We are told, and can readily believe it, that if toughened glass is taken the same care of as ordinary glass, breakage will be a very rare occurrence, and even in that case unusual violence will have to be brought to bear by throwing it about or striking it very heavily. From what we gather, the Toughened Glass Company, Limited, intend devoting their sole attention, at least for a time, to the production of window glass for Government and corporation buildings, railway and market roofs, mill, and other purposes of a similar nature. As toughened glass is not affected by any change of temperature, mill owners and others will find its use a great saving, for it is well known that the difference of temperature inside and outside of mills and works, more especially in winter time, causes ordinary glass to break and crack. Again, the sun's rays upon glass roofs often crack and break them, as one may see by examining any of the many railway roofs. Besides the purposes already named, toughened window glass will come largely into use for street lamps, sign writers, railway signal lamps, for photographers, and a variety of other purposes. Toughened glass cannot be cut with a diamond, but by machinery it can be both cut and polished, and we understand that toughened common window glass, cut and polished for such things as carriage lamps, looks quite as well as polished plate glass, and can be produced to sell under the price of the latter. Speaking of prices, toughened glass will naturally be dearer than common glass if used in the same thickness, but the Toughened Glass Company, Limited, intend applying their glass of a much less thickness to purposes where thick glass has been applied hitherto, and consequently it will be cheaper; for instance, a railway station roof, for which they employ at present rough plate half an inch thick; if toughened rough plate a quarter of an inch thick were used in its stead it would be some six or eight times stronger than the half inch, and the price would be considerably cheaper, as the cost of toughening would be much less than the difference in price between quarter and half-inch glass. Another great advantage to be gained by using toughened glass is, that architects will be enabled to erect much lighter structures to carry the glass. Such articles as dinner plates, dishes—in fact, all things which can be pressed or moulded—will be brought into the market so soon as the company have fully developed the window glass branch of their business. They are at present executing orders, at their works in Germany, for various descriptions of bottles, decanters, ale glasses, &c., and as this is a distinct branch of their trade, they do not intend transferring it to Stockport, as cheapness of materials, combined with cheap labour, more than compensates for the cost of carriage to this country. The bottles are of unusually great strength; indeed, those made of glass two millimetres thick (which is about the thickness of a wine bottle) will resist a pressure of 450 to 550 lbs. to the square inch, whilst those made four millimetres thick (say the thickness of a champagne bottle) will withstand a pressure of some 900 lbs. to the square inch. The works at Stockport, under the direction of Mr. John Jennison, assisted by a French engineer, are progressing very rapidly, and it is confidently anticipated that in the early part of July the company will be in a position to execute all orders entrusted to them.—*Cheshire County News.*

CHROMOTYPE CARBON PRINTING.

SIR,—Some months ago you favoured with a ready welcome two letters of mine despatched to your journal, and expressed the hope that any new experiences likely to be of value to the whole profession would be given freely to photographers in general, and not confined to the select circle of "Autotype Notes and Queries."

Well, I think I have got two points that are just worth noting, and one of them I consider of essential importance. Anyhow I shall throw them with a few remarks into general circulation, and as the matters are practical, any discussion that may follow will, I dare say, be of service.

First, let me say that my satisfaction with chromotype printing only increases. I positively find no difficulties,

and the favour of the public towards permanent prints augments every day. Not only in portraits, but in landscape work, chromotypes are demanded; and although Salisbury, having a whole rookery of photographers, has necessarily much competition, and prices miserably low, yet the public pay me, of their own choice, forty per cent. more for chromotypes than for silver prints, and do this not only because they are permanent, but also because they are more beautiful.

A little practice is necessary to estimate the printing quality of the negatives, and decide on the amount of exposure required, but this is soon obtained. We develop twelve cartes on a plate, and as our rule is never to under-print, but to reduce, if necessary, in development, with extra hot water, we come to the happy conclusion of not losing more than two or three per cent., and of having all the prints of such an equable depth of colour as cannot be managed with silver printing.

As to reticulation, I know nothing of it now-a-days. I perceive that the Autotype Company's tissue is tougher, less liable in hot weather to run in streaks when drying, and in several ways improved, and the present absence of reticulation may be due to this; but I have always differed with the Company's theory of the cause of reticulation, and feel sure that rapid drying has nothing whatever to do with it. Still, as reticulation is a fault that appears to belong only to the past, it is not worth further discussion.

For the summer weather, I find my suggestion of placing the bath solution in Winchester, wrapping a wet cloth round them, or allowing a stream of cold water to trickle over them for a couple of hours, reduces the bath to such a temperature as makes sensitizing quite safe. I hold also strongly to my expressed opinion to sensitize overnight, and only for the next day's consumption. I know thus exactly what I am about, and what to expect. If I chance to sensitize rather more tissue than wanted in the day, I simply throw it away. This I find to be the cheapest course.

Now, of the two items of information that I wish this letter to convey, the first point is very simple, and perhaps is more applicable to beginners. It is simply that when developing, and as soon as the paper has peeled off from the pigmented gelatine beneath, allow the plate to rest in the water for at least two minutes. The picture develops itself and gets intensity, and the danger of washing away some of the half-tone by the immediate lavement with hot water is wholly avoided. This is but a simple point; but I have known many beginners arrested at this stage by imperfect pictures, the cause of which I believe I have here stated.

My second point is, I consider, of great importance, and the statement of it will bring me a little in collision with the authorities at Ealing Dene. There was a time when I bowed humbly to the instructions of Mr. Foxlee, and have taken quietly several raps over the knuckles by Mr. Sawyer; but I am so satisfied with the results of my own observations, that I am not the least afraid to challenge an issue upon the point in question. This point is that the instruction in the "Autotype Manual" for preparing the sensitizing bath, by adding to one ounce of bichromate thirty ounces of water, is a mistake. This bath is too weak, and its use is the parent of a fruitful crop of difficulties. Of course I may be wrong, and I stand open to correction; but I never rush into print without carefully repeating my experiments over and over again, and this experience tells me that twenty ounces of water is the most that should be added to an ounce of bichromate. I consider this the *maximum*, and my practice varies from one in eighteen to one in twenty. I say that the feebleness of the image, the washing-up of high lights, and the loss of detail which bother photographers in carbon printing, are almost entirely due to the weakness of the bath. I am not chemist enough to say if the rule which gives a more vigorous silver print in a strong silver bath holds good in

the bichromate bath; but I am quite practical man enough to know that the bath to ensure good results, and to avoid a host of difficulties, is the strong bath, as indicated above. I have quite recently had a discussion with Mr. Foxlee on this point, and I have seen numbers of chromotype specimens done by the Autotype Company, and I say that from the same negatives in my strong bath I will get better results. I do not want to be one of the arguing sort, although I elect to stand up for my own opinions. The case is in a nut-shell; and I say to chromotype and carbon printers, try the strong bath instead of the weak one, and I think you will say that I have given a very useful and excellent piece of advice.

When I reflect, Mr. Editor, upon the absolute inexperience from which I started, I am surprised at my own success. Before I went to the Autotype Company's works, I had never touched carbon, and when I got there it was a day of terrific storm, and I felt half dazed with the novelty of the operations. However, I went home and tried, and tried, and tried. At the end of a month I said to myself,—"I am done. This chromotype will injure my health, spoil my temper, waste my money, and block up my business. I had better give it up." However—No. I thought I would have another trial, and in a fortnight after that, things began entirely to alter. My impression now, as a man of business, is, that the investment for a licence was the best photographic day's work I have ever done. It has increased my business, and added to my profits. It has led me to open a branch at Warwick, which at once succeeds by good permanent work; and I have farther, from my full persuasion in the matter, ventured on a considerable contract with the Autotype Company, and mean to push chromotype into fresh districts.

Hoping that my remarks may aid my brother photographers, and encourage the feeling that our work must be made permanent, I am yours, O. J. WILCOX.

Salisbury, Sept. 11th.

Talk in the Studio.

PERMANENT CARBON PHOTOGRAPHS.—It is only fit that the trade should impress upon the public the fact that these photographs are really as permanent as engravings. This once well known, the sale for such will be wonderfully increased. These prints in carbon will be perfectly distinct from prints in silver, and a print-seller may truthfully guarantee them being permanent as engravings. Therefore, to make such works popular, it is only necessary to put forward their cheapness and durability. Their effectiveness is apparent. Perhaps a little prejudice still exists against very large-sized photographs; but spacious rooms and halls require filling, and for such a purpose carbon photographs are well adapted.—*Stationer.*

ENGRAVED SURFACES ON METALS.—A pure silver surface is first taken, and after polishing, is exposed to the action of iodine, by which a film of iodide of silver is obtained. The plate thus prepared is then exposed to the action of the light under the photographic negative of the object to be reproduced until a faint image is obtained. The plate is then submitted to the action of an electrotyping bath, when a well-defined image of the subject will be obtained in copper—the latter depositing itself only on those portions of the plate that have been affected by the lights of the negative. The plate is next dried, and covered with an etching solution consisting of sulphuric acid and nitre (or their equivalents). This, it is affirmed at once attacks the shadows or exposed portions of the silver surface, while the electrotyped surfaces are not affected. After etching to the required depth, the copper deposit may be removed by *aqua regia*, bearing a finely etched image on the silver plate. To engrave on steel, copper, &c., it is first necessary to coat the surface with pure silver, after which the process is substantially the same as that above described, with such slight modifications in the etching solutions to be used as the nature of the metal employed would indicate.

CLEANING OF PLATES AND LENSES.—All persons who work in photography know, or should know, that to clean lenses, and to preserve the polish of their surfaces, they should not be wiped with a cloth, but after having removed the dust by means

of a brush, they should be covered with a thin coating of grease, then wiped with a piece of very soft chambray. An amateur asserts that for this purpose there is nothing better than chicken grease. Without contesting the merit of this fatty body, we simply use tallow, which we recommend not only for lenses, but also for plates which are to be collodionized. The dealers in glass plates for clichés coat them with grease, and simply wipe them before delivering them to photographers, and it is known that these plates generally give very pure clichés without any other cleaning. Many methods have been suggested for removing the varnish from old plates. A mixture of benzine and alcohol in equal parts, agitated and poured on the plates, generally acts very quickly and very well. The last traces of reduced silver which may yet adhere are then removed by iodized alcohol (alcohol 100, iodine 0.50). When the surface is properly cleaned it is rubbed over with the finger or a tuft of cotton lightly impregnated with tallow, and wiped dry. Plates thus prepared may be kept indefinitely, and are protected from dampness, the enemy which too often interposes itself between the collodion and its support. It is well to rub the plates, whatever may have been the previous mode of cleaning, with a little talc, which increases the adhesion of the sensitized coating, and does away with the gelatine or albumen, the use of which would otherwise be indispensable for the preparation of dry plates.—*Bulletin Belge.*

To Correspondents.

ONE WHO TRIES.—The silvery flakey scum which arises in developing is silver reduced to metallic form by some reducing agent present. It has been attributed to the use of impure acetic acid, containing some empyreumatic oil, which acts as a reducing agent, tending to fog. We have generally found it arise when using old and somewhat decomposed collodion. In this case the image is often thin and poor. 2. We have not met with the black streaks from the edges which you describe. They probably arise from the plate being dirty at the edges, or possibly from warm and perspiring fingers.

G. CLIFFARD.—The use of the hand-screen for controlling lighting cannot be verbally taught. It might be taught in practical lessons, or learnt by observation. As a rule, to use it efficiently requires experience, and this can only be obtained by trying. If a photographer have any idea of what effects of lighting he wishes to secure, he will soon be able to apply the hand-screen to the end required. 2. You speak of lighting *Rembrandts* as though some fixed rule existed as to their lighting. Sometimes they are chiefly lighted from the top, sometimes from a side-light in front, sometimes from a side-light behind. 3. It is wise, in replenishing a toning bath, to add all the same materials in the same proportions as at first, using, however, only one-third of the proportion of water.

B. L. F.—A very small proportion of chloride of silver distributed through a large quantity of water precipitates very slowly. Add a little nitric acid, shake, and then give it time. Do not add washing waters of prints which show little trace of silver, and generally avoid getting too much water with your chloride.

A. WILCOX.—Sprays and branches of trees may be kept in reasonably good condition by placing the stalks in water, changing the water every day, if the leaves require to be kept so long. The addition of a little ammonia to the water will revive the leaves when they show signs of falling.

H. B. F.—The paper you sent contains not a latent or undeveloped image, but the traces of an image which has faded out. At present there is no method known by which such an image may be brought back again. This is a subject well worthy of the attention of experimentalists. The material of the image is there, but it has lost its colour, and it is more than probable that under suitable treatment the dark colour might be restored. But little has been done in this direction, and at present no method of effectually restoring thoroughly faded photographs is known.

CRYSTAL.—The crystallized surface assumed by your tins on drying is due to excess of bichromate. You have either used the solution too strong, or allowed the tins to remain too long in contact with it.

A. KIMBLEY.—The glass house of which you send diagram will answer very well for amateur purposes. For busts, &c., it will be better than a larger studio. For full-length figures, groups, &c., you will need to take the camera outside, as you propose. Take care, in such case, to use a large hood to the lens, or some contrivance to shut off excess of light entering it. Always remember that the lens is a window admitting light into the camera, as well as an objective forming an image. We presume that the glass side of your studio will face the north. You need not then have any in the south side, but must use reflecting screens, which, skillfully used, will give good results.

Several Correspondents in our next.

The Photographic News, September 21, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO. SPECIAL PHOTOGRAPHIC CORRESPONDENTS—PHOTOGRAPHIC LITERATURE—INTENSIFYING NEGATIVES.

Special Photographic Correspondents.—What are photographers doing at the theatre of war? Why have we no pictures from enterprising disciples of the camera? What would not some of us give to have a good photograph of the Sistova bridge, that narrow fragile span across the Danube which represents the weakest link in the Muscovite chain of occupation. It would be something to see a rapid photograph taken of this structure, of the artillery and train crossing, of reinforcements going to the front, of provisions and ammunition waggons threading their way across. Such a picture would give us here at home a better idea of the difficulties of war than columns of descriptive letterpress. People would then learn under what difficulties the Russian host is waging war, and realise how serious a thing it is to feed an army, and keep it going. Then, again, we want to see a camp, a real bivouac placed before our eyes. We want to see a group of Cossacks with their horses picketed in the background, or a pack of Bashi-Bazouks performing the duties of outposts. What sort of encampments do the soldiers construct in Bulgaria? Have they tents to sleep in, and what sort of tents? Do they entrench themselves, and place guns in position for protection? Have they field telegraph trains, pontoons for crossing rivers, and ambulance waggons? All these questions a series of photographs would answer in a moment, and how eagerly they would be scanned and paid for need scarcely be said. There is no need for the photographer to go to the front. Besides the risk of danger, there is the difficulty he would have in transporting his apparatus and paraphernalia. He would not need to go very far to seek food for the camera. Indeed, at the front we fear there would be few pictures to take. A stretch of gray, uninteresting country, with the enemy's lines barely visible a couple of miles or so in the distance, would make but a very poor picture in the camera, and would probably be of little value, either on the score of military or general interest. Camp scenes, such as any active man provided with passport and means could secure without difficulty, are what is wanted, and we are surprised, indeed, that no photographs of the kind are to be seen in our capital. The correspondents of illustrated papers need not be interfered with, for they do work which the photographer is incapable of performing, in the same way precisely as the camera can perform wonders which the pencil of the draughtsman fails altogether to depict. The field photographer could learn, however, something from the artist-correspondent. He would find that the latter does not care so much about depicting distant redoubts and long stretches of country, for when all is said and done, such pictures are of little interest; the representative of an illustrative paper seeks out a characteristic group, and from this he works up a telling scene. An ambulance waggon passing to the rear, a wounded man even, is frequently enough for the main feature of a picture, and minor details are soon filled in. If we have one incident truthfully set before us, we have but to multiply it in our mind in order to get a general idea. So it would be with the photographer if he went on the field. It would be little good, even if he were in a position to do so, to give us an instantaneous view of a fight some thousands of yards off. We might actually see a little fog representing smoke and dust afar off, but it would be the foreground that would constitute the picture. And if we did not see a disabled gun or a few marks of strife littering the ground, the view would fail to convey the slightest idea of a battle-field. The best war pictures we know of, photographs showing really that there has been a struggle, are some relating to the Chinese war of 1860; these represent the interior of the Taku forts, and bear a very truthfu

impress upon them, even if the score or so of Chinese dead were not there to tell you of the terrible fight that has just taken place. Another photograph, scarcely less vivid in demonstrating the fierceness of a war struggle, is shown in a photograph taken by Robertson, of the interior of the Redan after the terrible fighting, and its ultimate occupation by the British. Why cannot photographers do what they did fifteen and twenty years ago? We do not want battle-fields and scenes of horror, but we should like to see with our own eyes something of camp life, of an army on war footing; and this a field photographer could enable us to do. We should not then get our news at second hand, reading it in the newspapers, but could be in a position to view scene after scene as if we were in the field ourselves. Such photographs, too, would help us to comprehend far more readily the graphic letters that appear in our contemporaries, and to realise, as we have said before, the obstacles that have to be overcome and the hardships and privations to be undergone. It is said that, as special correspondents increase, wars will grow more rare, because the miseries and terrible realities of war are brought home more vividly to the people. If this is really so, would not photographers in the field work still more good by sending us the shadows actually of the scenes themselves?

Photographic Literature.—Another German photographic journal has come into being, called the *Deutsche Photographen Zeitung*, the editor of which is Herr K. Schwieler, of Weimar. It is to be a weekly paper from the first of January next, fortnightly till that time, and will constitute, therefore, the only weekly photographic journal in Germany unless the *Wochenblatt* is still in existence. Besides the *Zeitung* there are now five other German photographic journals published, namely: the *Correspondenz* and *Notizen*, of Vienna; the *Mittheilungen* and organ of the German Society for the Advancement of Photography; the *Archiv*, edited by Dr. Liesegang, at Elberfeld; and the *Anzeiger*, of Munich. The *Correspondenz* is the organ of the Vienna Society, and Dr. Hornig the editor thereof; while Dr. Vogel, the President of the Berlin Society, undertakes the editing of the *Mittheilungen*—these two, as our readers may know, being the principal journals printed in the German language. In France are to be found just now four journals, but only two of them, the *Moniteur* and the *Bulletin*, are of any particular value; Belgium has two journals, Holland, two, Italy one, and Denmark one. In America five journals appear, and in Great Britain three, two weekly and one monthly, during the session of the Photographic Society. As the English journals are more voluminous than most of the foreign photographic papers, and appear, too, weekly, more information is, without a doubt, published in this country than elsewhere.

Intensifying Negatives.—M. J. M. Eder's experiments in this direction may be summed up in a few words. In the method of intensifying negatives with potassium ferricyanide and a lead or uranium salt, nothing has hitherto been known of the reactions which take place. To investigate the reasons of the intensifying, the author acted on freshly precipitated silver with a solution of potassium ferricyanide, and found the following reaction to take place:—

When heat is applied, the mixture smells of hydrocyanic acid, and silver goes into solution. In presence of lead or uranium salts, lead or uranium ferrocyanide is formed:

Ferric salts cause a precipitate of Prussian blue, and with ferricyanide, of Turnbull's blue in the negative; this occurs either on silver or platinum negatives. As 2 equivalents of silver precipitate 6 of lead or uranium as ferrocyanide, while only 1 atom of platinum is precipitated by 4 of silver, 1 of gold by 3 of silver, and 1 of mercury by 2 of silver, it is evident that a greater intensification may be produced by means of lead or uranium, than with these metals.

PICTURE FRAMES AND THEIR MANUFACTURE.*

"Paste.—Mix one tablespoonful of wheat flour with half-a-pint of cold water, adding the latter gradually, and thoroughly stirring in each portion before pouring in more; place the vessel over the fire and stir the whole assiduously until it boils; great care should be taken to prevent caking or burning on the bottom. An addition of half-a-teaspoonful of powdered alum will strengthen the product. The addition of a few grains of corrosive sublimate, or a few drops of creosote, will prevent it from turning mouldy, and keep insects away. When too hard or dry it may be softened by beating up with a little hot water.

"Mitring Picture Frames.—In order to obtain instruction in the art of making picture frames, we will go into a shop where the frames are mitred together, fitted up, and turned out to be hung in the cottage or hall, and where all the frames from the gilder's shop adjoining come to be fitted up and completed. As we see two or three very busily engaged in various occupations, we will not interrupt them for the present, but take a critical survey of the shop. It is lighted by windows on two sides, and a stout wide bench runs under the windows round two sides of the room. At certain distances we see bench vices fastened, at some of which are men busily at work. Down the middle of the shop is another wide bench, and on it we see rolls of engravings, and some are fitted into frames. At the end of the room is a small circular saw driven by the foot, and on the opposite side of the shop a good stock of mouldings are arranged on bars let into the wall. We see four or five sizes and qualities of O.G. maple, a variety of patterns of inside slipping, beads, &c., in German mouldings, and a good stock of mouldings in the white ready to be joined before going in to the gilder; also gold mouldings packed in white paper.

"In a room adjoining this shop a man is seen busily employed packing a lot of pictures in cases ready to be sent out. The occupations of the men are various, and a division of labour seems to be the order of the day, as we see one actively employed in joining a large lot of maple frames with a large number down by his side; another is 'shooting' the moulding, while a third is cutting up mouldings. But we see a man in the centre of the shop looking over a book, and as he has a good-natured open countenance, we will draw near and see what he will say to us in answer to enquiries as to what his occupation generally is. He informs us that he is constantly employed in 'fitting up' all the best of the miscellaneous work, and that, in consequence of his work requiring great care, he does not get through so much. He fits up the gold frames finished in the gilder's shop with expensive chromes, proof engravings, oleographs, and oil paintings; he also fits up the best work in water-colour drawings, and is trusted with proofs and pictures to mount, some of which are worth as many guineas as there are days in a month.

"He informed us that he was called a 'fitter-up,' and that it was not his work to make frames, although he might be able to do so. As he had satisfied himself as to the work in hand, he was about to hand the book over to a man in another room who did 'mitring-up,' and he offered to show us the way.

"Our friend the 'fitter-up' was not aware we had been engaged for a number of years in gilding, and in a fine art repository, so treated us to a sight of some of the best chromes, little thinking they were old acquaintances, and that we had times before taken a pride in turning them out as he would do—first class.

"We were received by the man about to execute the orders in the book with civility, and he looked superior to the general class of men engaged in the trade. As we stayed with him some time we will describe the execution of the work required.

"As 'Frith's Derby Day' was wanted at once, he set to

work to cut out the mouldings, and mitre them up. It was to be framed in the best O.O.G. maple, with a broad gold flat and hollow inside, and the picture mounted on a stretcher. The sight edge of the inside gold, to allow of the requisite margin, must be 57½ by 29; and, unpaparing some broad gold, flat and hollow, he carefully cut out on the saw-block four pieces a little longer than the required length, to allow of 'shooting.' He next selected some of the best maple, O.O.G., and cut one end off on the saw-block to the required angle. He next took one of the pieces of gold flat and hollow, and placed it on the rabbet of the maple, and marked the length a little beyond the gold flat, and cut off the length. This he did with the three other sides. The 'shooting board' was next required, when he placed first the maple in position, and, with his plane, which had a good edge, took off enough to secure a good surface, and in the next place a clean top edge to the mouldings. The next piece selected for the same operation was the piece corresponding in length, and after planing to his satisfaction, he measured the two pieces by putting the two sight edges together and making them exactly of a length.

"Before shooting the gold flat (and hollow, he said he should put the maple together, so that they could more easily make the mitres in both to run straight.

"Taking the four pieces of moulding, he went to the bench vice, and fastened one of the long pieces therein with the rabbet outside, and the right hand end very near the jaws of the vice. He next took up one of the short lengths in the left hand, and placed the two ends together. The two pieces were not placed exactly together, but the piece in the left hand was brought back from the sight edge about one-twentieth of an inch. When he had satisfied himself as to the exact position, holding the two tightly together, he with a bradawl decisively made a hole long enough to go into the moulding in the vice. When this was done he enlarged the hole in the piece he held by a gimlet, so that the size cut brads would drive easily through it without much friction or danger of splitting the wood. A little thin glue was then applied, and the moulding placed together as before, holding it very tightly together, when a brad of the requisite length, about two and a-half inches long, was inserted and driven home. In driving home the brad the moulding held by the hand was found to have moved forward a very little by the force of the blows, and thus a capital mitre was made; a second brad was then driven home, and both punched below the surface. Had the brad been driven home with the mouldings exactly level this would not have been the case.

"The other two pieces were then joined in the same way.

"Two mitres having been made, two more remained to be put together. He then took one half of the frame and fastened it in the vice near one of the unmitred ends, and with the assistance of a lad on the other side of the bench he brought the two joined pieces together in their proper places, and with the bradawl and gimlet made the hole as above described; he then took the half out of the vice and put in the other half in the same way, and made the hole in the fourth mitre. He next glued the two ends of the piece out of the vice, and with the help of the lad brought the two halves together, and quickly and steadily drove home the brad. The frame was then taken out of the vice, and the other mitre attended to in the same way, and a second brad inserted, and the two punched below the surface. The frame was again put in the vice for the third mitre to have a second brad driven in, when both were punched below the surface, and the frame was found to be well and neatly put together. Rather thin glue was used, and he was careful not to put on too much, so that it would appear on the top of the mitres (see fig. 8.)

"Having so far completed the maple frame, he at once proceeded to mitre up the inside gold flat. Before taking it in hand he put on his left hand a glove made of chamotte

leather, explaining at the same time that in shooting and mitreing up gold mouldings, some of which were gilt down to the back edge, it was necessary to protect the gold from the heat of the hand, as inattention to this would be sure

Fig. 3.

to damage a frame which was expected to be turned out in the best manner. He said also that a piece of soft cloth was glued down on the shooting board to prevent any scratches on the gold, and that he was particular to keep it free from shavings and grit.

"After seeing well to his plane-iron, the gold flat was soon ready for mitreing, and it was noticeable that he was very particular to get the length of the pieces, so that the frame would just take half of the rabbet, and the mitres by that means would range exactly. With his left hand still covered by a glove, he handled the moulding and mitred it up in the same way as before mentioned for the maple frame, and when completed the mitres looked like a hair across the corners.

"He next took the rabbet measure of the frame just mitred, and at once proceeded to cut out a stretcher from a large number of lengths of deal cut ready for the purpose.

"In marking out the stuff for the stretcher he explained that there was no waste, as in the ordinary moulding, as the length was cut from one side and the other, avoiding the cutting out of the triangular piece necessary to make the mitre. He also informed us that he knew it was the fashion in many country shops to make a stretcher by halving it together, but that a mitred stretcher was stronger, more expeditiously made, and was much neater than those made in such a way.

"He then 'shot' the lengths as usual, and soon put them together in the vice as before described, and fitted it into its place in the rabbet of the gold flat. The three frames placed one in the other were ready to go in to the fitter-up.

"Sometimes with O.G. maples the lengths are found to be warped, and when cut into the required lengths by the picture frame maker and made up, the frame is found to be twisted and the mitres bad. Mouldings should be kept flat before they are used.

"Where gold mouldings are gilded down the back edge, it will be necessary to lay in the vice some slips of wood covered with cloth, to prevent marking the moulding.

"There is a very good mitreing machine suitable for picture frame making in use in many shops, which does the work very well.

"We have described mitreing up a large frame, but smaller ones will not require the gimlet to be used before joining, as there is not the danger of the moulding splitting where small brads are used.

"Gilt slipping for the inside of maple, rosewood, oak, or other frames, requires care in mitreing up, owing to the thinness of the wood. Sometimes the wood will split, therefore the brads selected must not be too large, and the mitred pieces must be handled tenderly till the glue is dry. Where it is twisted or warped it is almost impossible to make a neat mitre, which is often the case with German mouldings.

"Oxford Frames.—These frames have become favourites within the last few years. They are made of oak with cross corners, and are got up in fancy patterns, some of which are finished with ultramarine on the bevels. They can be had of the wholesale houses of the following sizes:—

4½ inches by 3½ inches		16 inches by 14 inches	
7	" 5½	18	" 16
8	" 6	21	" 14½
10½	" 8	23	" 18½
12	" 10	29	" 21
14	" 12		

"They should be rubbed over with linseed oil, which will give the wood a richer appearance.

"Corners on German Frames.—On frames made from the best German mouldings, composite corners, gilded, look very well and will wear well. When the corners are ready it will be necessary to scrape the corners of the frame down to the whitening, or the ornaments, when glued on and backed up, will peel up. After backing up, gild in oil. We have seen brass corners on German frames, but they would look much better without any ornament than such unsightly things."

ON SOME PROPERTIES OF GLASS.

GLASS—whether in the form of the lens in the camera, or the support for the film in the negative, or, indeed, in any of the many shapes in which it is applied to photographic use—is looked upon as a substance of such complete permanency and unalterability that it is possible we may be thought guilty of exaggeration when we say that to find a glass which has a just claim to this popular opinion is very far from being an easy matter. That form in which the unblemished character of glass appeals most to the photographer is, naturally, the negative plate, of which some hundreds of thousands must be used annually; and so much does the common idea rule manipulative practice that it is scarcely too much to say that it is more than likely that the poor, much-abused bath is credited with many a vagary when it is perfectly innocent, and some chemical alteration of the glass is the source of the evil.

That glass is so liable to be altered a little reflection upon the difficulties found in plate-cleaning will show; for when a case arises where stains, &c., unmistakably point to the glass as the cause, it is evident its surface has not been mechanically abraded or scratched, and the change, whatever it is, must be of a chemical origin, though, possibly, mechanical in its immediate effect upon the deposition of the silver forming the image. We purpose to give some idea of the character of the metamorphosis is likely to be undergone by glass when exposed to the action of air or water. Forewarned is to be forearmed, and the deeper we are able to dip into the source of failures the more power do we obtain to prevent them.

Glass forms an interesting example of the fact that, whenever special excellence in a particular direction is to be attained, it must usually be at the expense of some quality or other. The various characteristics of glass—its hardness, lustre, permanency, insolubility, impressibility, &c.—prove this. It is in the main a silicate of soda or potash, or both, having combined with it other silicates, such as those of lime, alumina, baryta, &c. There is a glass made (silicate of soda) which is quite soluble in water—it has a beautiful sea-green hue as generally found in commerce—and between it and the most insoluble varieties, containing silica and aluminium in large proportion, there are all varieties of solubility to be found. Silicates of lime or potash separately are acted upon by water and acids, but, fused together, they are insoluble. The greater the proportion of silica and alumina glass contains the more insoluble it becomes, and it is the manufacturer's province so to proportion the ingredients of his glass as to

produce qualities most suitable for the object in view. In this country glass manufactured in Germany, France, and at home is to be purchased, and each has its peculiar characteristics. An extremely pale glass, almost colourless, was imported a number of years ago from Germany; but it gave way to the action of the atmosphere to a most remarkable extent, and we have for some years seen nothing of it.

It has frequently been stated that glass with an artificial surface—that is, one produced by polishing with abrasive powder—is less clean to work, and more liable to stain, than one with the natural surface first obtained after the sheet has cooled down. Though we believe it quite possible that more has been made of this difference of surface than the actual facts warrant, we can yet easily see why, apart from the supposed hardness of the hypothetical skin, artificially polished glass should be more readily acted upon by water or other chemicals. This surface being entirely given by a process of rubbing, or, as it were, minute scratching with a powder, it might be supposed that if it could be examined by a microscope it would be found rough, like "obscured" glass, and thus offer a greater amount of surface to be acted upon.

The action of water upon glass is to decompose it, the potash and soda and a little silica being dissolved; and the greater the amount of alkali present the quicker is the decomposition brought about. The action of the atmosphere is of a similar nature, the moisture always present to a greater or less degree being the real active agent; the common result is to separate the soda and potash, and to leave the silica upon the surface sometimes in a manner that is only perceptible upon heating, when excessively minute flakes separate and leave a dull surface. It has been stated that glass buried deep in the earth has been, when dug up, so soft as to be cut with a knife.

The use of soda for cleaning old glass plates is often recommended, and in its way, and with proper precautions, it is very useful; but it is to be remembered that it dissolves the silica of the glass, acting with greater or less effect according to its strength and temperature. If this be borne in mind many troubles will be avoided, numerous cases of ineradicable stains having been traced to overlong soaking in alkaline solutions. If proof were needed of the solvent and injurious powers to small quantities of water, if continued for a sufficient length of time, it will be only necessary to breathe upon one-half of a piece of patent plate glass, and, after immediately covering the film of condensed moisture by another plate to wrap up the two, place in a cold place for a twelvemonth, and then examine. The moistened part will be roughened to such an extent as almost to take the mark of a blacklead pencil. We have seen packets of several gross of plates entirely ruined from this cause; glass plates brought out of a cold store room into a damp atmosphere had condensed the moisture of the air upon their surfaces, and the packer had packed them without wiping them, as, indeed, it was scarcely likely he would think of doing. They remained immersed for a considerable time, and when opened were found to have the surface visibly eaten into, not a glass remaining that was fit for use; and there can be no doubt that there must be large quantities of glass similarly injured, though, unfortunately, not visibly so, the mischief only being observed after taking the negative.

Again; if further proof were required of the solubility of glass—that is, its decomposition, which must result in disintegration, and thus roughen the surface, if even microscopically, and render it liable to retain foreign matter—it would be found by boiling in a Bohemian glass vessel a weak alkaline solution in which litmus had been dissolved, and acid afterwards added to produce a faint reddening. The result would be that sufficient alkali would be dissolved out of the glass to restore the blue color to the litmus. This same experiment can be proved in a

homely way by adding a little red cabbage to distilled water, and boiling in such a vessel, when the distinct blue of alkali would be given to the water.

We think we have advanced sufficient facts to show that glass is by no means the unalterable substance commonly supposed. If it induce a little more care in the use of this necessary photographic adjunct our purpose will be served.—*Scientific American*.

AFTER-EXPOSURE WITH VIOLET LIGHT.

M. SCOTELLARI AMONG THE BERLIN PHOTOGRAPHERS.*

As may be inferred from our last number, M. Scotellari the proposer of violet-lighted studios, was in Berlin in the month of July. He desired to find purchasers for a new instantaneous process, and during his sojourn in the Prussian capital experimented repeatedly in the studios of Messrs. Loescher and Petsch, and of Messrs. Reinhardt and Lindner, in the presence of many photographers who were invited to witness the demonstrations; none of the latter were, however, attended with particular success. A part of his secret was, however, patent: to wit, a transparent cap for the lens, the top of this cap being merely covered with a thin sheet of violet tissue-paper. Such a tissue-paper may be easily prepared by any photographer if he dissolve aniline violet in alcohol, and having diluted some of the colouring matter with water, dip a sheet of tissue-paper into it. Through this thin sheet of violet paper, or diaphragm, an after-exposure of the plate takes place, such an after-exposure as has been frequently described in this journal before; so that this feature of the Scotellari method is certainly not new.

Whether the other parts of his process (he employs, so he told us, neutral collodion, neutral developer, and neutral silver bath) can establish a claim for novelty is doubtful. One thing, however, is certain, that the process, in his own hands, gave unfavourable results at the time he visited Berlin. After these unsuccessful results (not six gave even signs of tolerable success) M. Scotellari declared that he would begin all over again. He presented a testimonial, with the signature appended of J. C. Schaarwächter, according to which some recent experiments had been made in that gentleman's studio with astounding results. On a close examination of the certificate it was found to emanate, not from the head of the firm himself, who was away, but from a clerk whose knowledge of photographic matters was limited.

Messrs. Reichardt and Lindner have, however, again made experiments with the violet lens-cap, after exposing their own plates, and they report the result to be favourable. A double cabinet plate was exposed, one half fifteen seconds, the other ten seconds, with a living model. The latter half, which had received less exposure, was subsequently exposed to violet light through the Scotellari cap, and, in the end, gave a softer and more detailed image than that portion of the plate which had received an exposure of fifteen seconds.

The exposure with the Scotellari cap takes place while the violet diaphragm is closed with a round disc of cardboard. This disc may be moved round a point which lies at the edge of the cap. Scotellari exposes, first of all, with this cardboard disc, closing up the violet diaphragm altogether, and then turns the disc several times round its middle point, when, of course, the light entered through the diaphragm. He did this simply by guesswork, and it is no wonder, therefore, that unsuccessful pictures occasionally resulted, for if the after-exposure is not carefully calculated, there is danger of fogging the negative. This is the reason, undoubtedly, why experiments in after-exposure have only in isolated instances proved successful, and why, hitherto, the measure has only been resorted to at a pinch in order to help an under-exposed negative of a child, or improve the cliché of an unsteady sitter:

* Photographische Mittheilungen.

DRY BROMIDE OF SILVER EMULSION PLATES

BY F. WILDE.*

BROMIDE of silver emulsion plates are decidedly the best for dry collodion work, whether in respect to sensitiveness or trustworthiness of the films. As a general rule, the plates may be employed without being washed or treated with preservatives. During the recent hot weather which we experienced in June last I found, however, that plates which had been prepared some little while (and which previously gave good results) were hardly to be trusted, and I had hard work to get clear and brilliant negatives from them. I found, however, that the hot weather made little difference when a preservative was had recourse to, and I so treated my plates, therefore, in the summer, and with the best results.

The wet bromide emulsion film repels any aqueous preservative very stubbornly, and a good deal of moving backwards and forwards of the plate in the preservative solution is necessary before the fatty streaks disappear from the surface of the plate. All the preservatives, too, which I tried and applied to the wet films had the effect of lessening the sensitiveness of the emulsion. Alcohol preservatives are more easily applied; but these diminish the sensitiveness of the plates still further, and render the negatives thinner. Quite different, however, is it when the preservatives are applied to a dry surface. In that case but very little decrease of sensitiveness is to be perceived, and this only in exceptional cases; while in some instances the sensitiveness is much increased by the application of a preservative to the dry film. Of a long series of such substances, of which I have made trial, the best results were furnished by white of egg, gelatine, and a mixture of tannin and gelatine. Many of the well-known preservatives, again, we found to work more favourably upon admixture with gelatine.

The undermentioned mixtures have afforded me the best results as preservatives:—

1. White of egg diluted with eight or ten times its volume of water, and treated with sufficient glacial acetic acid to give it an acid reaction. The mixture is shaken violently, and after standing ten to twelve hours, when the clear fluid has separated, it is filtered through paper.

2. Water 400 cubic cents.
Glacial acetic acid 30
Gelatine 5 grammes.

The gelatine is swollen first of all with a little water, and then dissolved at a warm temperature, when the acid is added.

3. Solutions 1 and 2 mixed in equal proportions.

4. Water 100 cubic cents.
Tannin 2 grammes.

This solution is mixed with an equal volume of No. 2; the mixture is turbid, and, after eight to ten days' standing, a brown precipitate is formed. The solution is then filtered, and retains an odour of tannin.

By employing preservatives of the last kind (No. 4), very vigorous and intense negatives are obtained. Preservatives Nos. 1, 2, and 3 give softer negatives. When the preservative is washed, after application to the plate, the negative is always softer than when the former is not washed.

The treatment of the plates with the preservative is an easy matter, and soon done. The dry film may be moistened by pouring over it a mixture of thirty cubic centimetres of water and ninety of alcohol, which is afterwards washed off until the fatty streaks disappear, when the preservative is applied, being poured over two or three times successively. I prefer afterwards to wash my plates with a little spring water, so that on drying the plate has a matt appearance.

No one who has but a brief experience of emulsion bromide of silver plates can fail to value them very highly.

HOW TO PREPARE PHOTOGRAPHS FOR PRINTING BLOCKS.

IN the *Photographische Archiv* appear the details of a simple method of securing an outline photograph in metal suitable for printing with type in the ordinary printing press. It is necessary to be somewhat of a draughtsman, no doubt, in order to be able to do the work well and rapidly, although nothing is said on this head; but hardly anyone could, haphazard, undertake the matter.

Only a well-marked photograph with bold lines, and in which minor details are of no account, is suitable, and the negative is in the first place put into a camera or other apparatus, to furnish an enlarged positive. Upon this enlarged positive are traced, in Indian ink, the bolder lines which it is desired to retain, a pen or brush being employed for the purpose, according to the nature of the work or the desire of the draughtsman. After all details have been in this way traced with thoroughly black pigment, the lines of a thickness corresponding to the original object, and of such a nature as to be readily reproduced by photography, the print is treated with chloride of lime or other bleaching agent, and in this way was the whole of the image obliterated with the exception of the block lines made by the draughtsman.

The picture is now photographed, and in this way a small negative secured, or one, at any rate, of the dimensions of which the printing block is to be. In this case the negative will be perfectly opaque in the lights and transparent in the shadows, and from it may be easily produced, by any of the etching processes, an engraving upon zinc capable of being used in the printing-press with type.

Chloride of lime is specially mentioned as the bleaching agent wherewith to render invisible the details of the silver image after the draughtsman has done his work. We should think that a solution of bichloride of mercury would be much more effectual in making the original photographic image disappear.

A NEW GOLD SALT FOR TONING.

BY DR. J. ROHNSDORF.

UNTIL now there have been used only the single and double chloric salts of gold for toning. During the past winter Mr. Neumayer, student of chemistry from Munich, visited my establishment, and undertook under my directions the preparation of a gold bromide and a gold bromide of calcium, for the purposes of experimenting with these salts and their uses in photography.

Thin leaves of gold are readily dissolved in bromine water and in bromine gas. But a more rational and less disagreeable mode of preparation is by the action of hydrobromic acid, nitric acid, and aqua-regia.

During the evaporation of the gold bromide, which has a dark appearance and smells strongly of bromine, great care is necessary, owing to the fact that the gold bromide vaporizes more easily than the chloride. Bromide of gold is difficult to crystallize. By the addition of an exact equivalent of bromide of calcium dissolved in water, and evaporated, small granite-red crystals of double salts are obtained. $KBr + AuBr_3 + 5H_2O$ can be with difficulty dissolved in water; but a thin solution is of a deep red colour, and effloresces in dry air.

I have tried these double salts, also the gold bromide, with several additions, as a toning bath. In its general effect on silver copies it is analogous to gold chloride combinations, except that in the same proportions it acts more energetically.

The addition of soda bicarbonate gives a blue-black tone, melted acetate of sodium a purple coloured tone.

For a lasting gold bath, in form of a sol encaustic, these salts are recommended.—*Archiv.*

produce qualities most suitable for the object in view. In this country glass manufactured in Germany, France, and at home is to be purchased, and each has its peculiar characteristics. An extremely pale glass, almost colourless, was imported a number of years ago from Germany; but it gave way to the action of the atmosphere to a most remarkable extent, and we have for some years seen nothing of it.

It has frequently been stated that glass with an artificial surface—that is, one produced by polishing with abrasive powder—is less clean to work, and more liable to stain, than one with the natural surface first obtained after the sheet has cooled down. Though we believe it quite possible that more has been made of this difference of surface than the actual facts warrant, we can yet easily see why, apart from the supposed hardness of the hypothetical skin, artificially polished glass should be more readily acted upon by water or other chemicals. This surface being entirely given by a process of rubbing, or, as it were, minute scratching with a powder, it might be supposed that if it could be examined by a microscope it would be found rough, like "obscured" glass, and thus offer a greater amount of surface to be acted upon.

The action of water upon glass is to decompose it, the potash and soda and a little silica being dissolved; and the greater the amount of alkali present the quicker is the decomposition brought about. The action of the atmosphere is of a similar nature, the moisture always present to a greater or less degree being the real active agent; the common result is to separate the soda and potash, and to leave the silica upon the surface sometimes in a manner that is only perceptible upon heating, when excessively minute flakes separate and leave a dull surface. It has been stated that glass buried deep in the earth has been, when dug up, so soft as to be cut with a knife.

The use of soda for cleaning old glass plates is often recommended, and in its way, and with proper precautions, it is very useful; but it is to be remembered that it dissolves the silica of the glass, acting with greater or less effect according to its strength and temperature. If this be borne in mind many troubles will be avoided, numerous cases of ineradicable stains having been traced to overlong soaking in alkaline solutions. If proof were needed of the solvent and injurious powers to small quantities of water, if continued for a sufficient length of time, it will be only necessary to breathe upon one-half of a piece of patent plate glass, and, after immediately covering the film of condensed moisture by another plate to wrap up the two, place in a cold place for a twelvemonth, and then examine. The moistened part will be roughened to such an extent as almost to take the mark of a blacklead pencil. We have seen packets of several gross of plates entirely ruined from this cause; glass plates brought out of a cold store room into a damp atmosphere had condensed the moisture of the air upon their surfaces, and the packer had packed them without wiping them, as, indeed, it was scarcely likely he would think of doing. They remained immersed for a considerable time, and when opened were found to have the surface visibly eaten into, not a glass remaining that was fit for use; and there can be no doubt that there must be large quantities of glass similarly injured, though, unfortunately, not visibly so, the mischief only being observed after taking the negative.

Again; if further proof were required of the solubility of glass—that is, its decomposition, which must result in disintegration, and thus roughen the surface, if even microscopically, and render it liable to retain foreign matter—it would be found by boiling in a Bohemian glass vessel a weak alkaline solution in which litmus had been dissolved, and acid afterwards added to produce a faint reddening. The result would be that sufficient alkali would be dissolved out of the glass to restore the blue order to the litmus. This same experiment can be proved in a

homely way by adding a little red cabbage to distilled water, and boiling in such a vessel, when the distinct blue of alkali would be given to the water.

We think we have advanced sufficient facts to show that glass is by no means the unalterable substance so commonly supposed. If it induce a little more care in the use of this necessary photographic adjunct our purposes will be served.—*Scientific American*.

AFTER-EXPOSURE WITH VIOLET LIGHT.

M. SCOTELLARI AMONG THE BERLIN PHOTOGRAPHERS.*

As may be inferred from our last number, M. Scotellari, the proposer of violet-lighted studios, was in Berlin in the month of July. He desired to find purchasers for a new instantaneous process, and during his sojourn in the Prussian capital experimented repeatedly in the studios of Messrs. Loescher and Petsch, and of Messrs. Reinhardt and Lindner, in the presence of many photographers who were invited to witness the demonstrations; none of the latter were, however, attended with particular success. A part of his secret was, however, patent: to wit, a transparent cap for the lens, the top of this cap being merely covered with a thin sheet of violet tissue-paper. Such a tissue-paper may be easily prepared by any photographer if he dissolve aniline violet in alcohol, and having diluted some of the colouring matter with water, dip a sheet of tissue-paper into it. Through this thin sheet of violet paper, or diaphragm, an after-exposure of the plate takes place, such an after-exposure as has been frequently described in this journal before; so that this feature of the Scotellari method is certainly not new.

Whether the other parts of his process (he employs, so he told us, neutral collodion, neutral developer, and neutral silver bath) can establish a claim for novelty is doubtful. One thing, however, is certain, that the process, in his own hands, gave unfavourable results at the time he visited Berlin. After these unsuccessful results (not six gave even signs of tolerable success) M. Scotellari declared that he would begin all over again. He presented a testimonial, with the signature appended of J. C. Schaarwachter, according to which some recent experiments had been made in that gentleman's studio with astounding results. On a close examination of the certificate it was found to emanate, not from the head of the firm himself, who was away, but from a clerk whose knowledge of photographic matters was limited.

Messrs. Reichardt and Lindner have, however, again made experiments with the violet lens-cap, after exposing their own plates, and they report the result to be favourable. A double cabinet plate was exposed, one half fifteen seconds, the other ten seconds, with a living model. The latter half, which had received less exposure, was subsequently exposed to violet light through the Scotellari cap, and, in the end, gave a softer and more detailed image than that portion of the plate which had received an exposure of fifteen seconds.

The exposure with the Scotellari cap takes place while the violet diaphragm is closed with a round disc of cardboard. This disc may be moved round a point which lies at the edge of the cap. Scotellari exposes, first of all, with this cardboard disc, closing up the violet diaphragm altogether, and then turns the disc several times round its middle point, when, of course, the light entered through the diaphragm. He did this simply by guesswork, and it is no wonder, therefore, that unsuccessful pictures occasionally resulted, for if the after-exposure is not carefully calculated, there is danger of fogging the negative. This is the reason, undoubtedly, why experiments in after-exposure have only in isolated instances proved successful, and why, hitherto, the measure has only been resorted to at a pinch in order to help an under-exposed negative of a child, or improve the cliché of an unsteady sitter.

* Photographische Mittheilungen.

DRY BROMIDE OF SILVER EMULSION PLATES.

BY F. WILDE.*

BROMIDE of silver emulsion plates are decidedly the best for dry collodion work, whether in respect to sensitiveness or trustworthiness of the films. As a general rule, the plates may be employed without being washed or treated with preservatives. During the recent hot weather which we experienced in June last I found, however, that plates which had been prepared some little while (and which previously gave good results) were hardly to be trusted, and I had hard work to get clear and brilliant negatives from them. I found, however, that the hot weather made little difference when a preservative was had recourse to, and I so treated my plates, therefore, in the summer, and with the best results.

The wet bromide emulsion film repels any aqueous preservative very stubbornly, and a good deal of moving backwards and forwards of the plate in the preservative solution is necessary before the fatty streaks disappear from the surface of the plate. All the preservatives, too, which I tried and applied to the wet films had the effect of lessening the sensitiveness of the emulsion. Alcohol preservatives are more easily applied; but these diminish the sensitiveness of the plates still further, and render the negatives thinner. Quite different, however, is it when the preservatives are applied to a dry surface. In that case but very little decrease of sensitiveness is to be perceived, and this only in exceptional cases; while in some instances the sensitiveness is much increased by the application of a preservative to the dry film. Of a long series of such substances, of which I have made trial, the best results were furnished by white of egg, gelatine, and a mixture of tannin and gelatine. Many of the well-known preservatives, again, we found to work more favourably upon admixture with gelatine.

The undermentioned mixtures have afforded me the best results as preservatives:—

1. White of egg diluted with eight or ten times its volume of water, and treated with sufficient glacial acetic acid to give it an acid reaction. The mixture is shaken violently, and after standing ten to twelve hours, when the clear fluid has separated, it is filtered through paper.

2. Water 400 cubic cents.
Glacial acetic acid ... 30 "
Gelatine 5 grammes.

The gelatine is swollen first of all with a little water, and then dissolved at a warm temperature, when the acid is added.

3. Solutions 1 and 2 mixed in equal proportions.

4. Water 100 cubic cents.
Tannin 2 grammes.

This solution is mixed with an equal volume of No. 2; the mixture is turbid, and, after eight to ten days' standing, a brown precipitate is formed. The solution is then filtered, and retains an odour of tannin.

By employing preservatives of the last kind (No. 4), very vigorous and intense negatives are obtained. Preservatives Nos. 1, 2, and 3 give softer negatives. When the preservative is washed, after application to the plate, the negative is always softer than when the former is not washed.

The treatment of the plates with the preservative is an easy matter, and soon done. The dry film may be moistened by pouring over it a mixture of thirty cubic centimetres of water and ninety of alcohol, which is afterwards washed off until the fatty streaks disappear, when the preservative is applied, being poured over two or three times successively. I prefer afterwards to wash my plates with a little spring water, so that on drying the plate has a matt appearance.

No one who has but a brief experience of emulsion bromide of silver plates can fail to value them very highly.

HOW TO PREPARE PHOTOGRAPHS FOR PRINTING BLOCKS.

In the *Photographische Archiv* appear the details of a simple method of securing an outline photograph in metal suitable for printing with type in the ordinary printing press. It is necessary to be somewhat of a draughtsman, no doubt, in order to be able to do the work well and rapidly, although nothing is said on this head; but hardly anyone could, haphazard, undertake the matter.

Only a well-marked photograph with bold lines, and in which minor details are of no account, is suitable, and the negative is in the first place put into a camera or other apparatus, to furnish an enlarged positive. Upon this enlarged positive are traced, in indian ink, the bolder lines which it is desired to retain, a pen or brush being employed for the purpose, according to the nature of the work or the desire of the draughtsman. After all details have been in this way traced with thoroughly black pigment, the lines of a thickness corresponding to the original object, and of such a nature as to be readily reproduced by photography, the print is treated with chloride of lime or other bleaching agent, and in this way was the whole of the image obliterated with the exception of the block lines made by the draughtsman.

The picture is now photographed, and in this way a small negative secured, or one, at any rate, of the dimensions of which the printing block is to be. In this case the negative will be perfectly opaque in the lights and transparent in the shadows, and from it may be easily produced, by any of the etching processes, an engraving upon zinc capable of being used in the printing-press with type.

Chloride of lime is specially mentioned as the bleaching agent wherewith to render invisible the details of the silver image after the draughtsman has done his work. We should think that a solution of bichloride of mercury would be much more effectual in making the original photographic image disappear.

A NEW GOLD SALT FOR TONING.

BY DR. J. SOHNAUSE.

UNTIL now there have been used only the single and double chloric salts of gold for toning. During the past winter Mr. Neumayer, student of chemistry from Munich, visited my establishment, and undertook under my directions the preparation of a gold bromide and a gold bromide of calcium, for the purposes of experimenting with these salts and their uses in photography.

Thin leaves of gold are readily dissolved in bromine water and in bromine gas. But a more rational and less disagreeable mode of preparation is by the action of hydrobromic acid, nitric acid, and aqua-regia.

During the evaporation of the gold bromide, which has a dark appearance and smells strongly of bromine, great care is necessary, owing to the fact that the gold bromide vaporizes more easily than the chloride. Bromide of gold is difficult to crystallize. By the addition of an exact equivalent of bromide of calcium dissolved in water, and evaporated, small granite-red crystals of double salts are obtained. $\text{KBr} + \text{AuBr}_3 + 5\text{H}_2\text{O}$ can be with difficulty dissolved in water; but a thin solution is of a deep red colour, and effloresces in dry air.

I have tried these double salts, also the gold bromide, with several additions, as a toning bath. In its general effect on silver copies it is analogous to gold chloride combinations, except that in the same proportions it acts more energetically.

The addition of soda bicarbonate gives a blue-black tone, melted acetate of sodium a purple coloured tone.

For a lasting gold bath, in form of a sol encausé, these salts are recommended.—*Archiv.*

THE PRINTS WHICH HAVE FADED.

A WELL-KNOWN chemist and metallurgist, who took an active interest in the progress of photography in its early days, recently remarking upon the energy devoted to the perfection of carbon printing, observed that whilst that was a good work, a still more important field, in his opinion, remained altogether uncultivated. One of the highest prizes, both in praise and profit, remained open, he thought, to the man who should discover a certain and efficient method of restoring faded prints. This, he added, he had no doubt was quite possible, as the image still undoubtedly remained; it had changed, but nothing was lost. The silver and gold of which the picture consisted in its pristine beauty were there in the image still, but their condition was changed, and with change of condition had come change of colour. Any agent which would restore the former condition would restore the colour, and the picture would again be resplendent with the bloom of its young beauty.

It is indeed marvellous how little has been done in this direction, when it is remembered how valuable such a method would be; and that wealth would probably await the discoverer should he be fortunate enough to defend his discovery from the nibblings of those who knew all about it before, and stigmatized it as neither new, nor true, nor useful! It is probable that a considerable amount of intelligent experiment would be necessary. The path is not quite plain theoretically, inasmuch as the precise nature of the change undergone by a print in the process of fading is not well ascertained. But there are two methods which have been tried with some degree of success for restoration of faded prints, which are worth further attention, especially as it is probable that many of the young and enthusiastic photographers of the present day may not be familiar with methods to which but little attention has been given.

The methods which have been tried have, curiously enough, never come into general practice, probably because whilst considerable improvement is effected upon the faded print, it is not absolutely restored to its original condition. The first method consists in treating the print with bichloride of mercury. The faded print is immersed in a weak solution of bichloride of mercury (one grain of the bichloride to an ounce of water will serve). Or another mode of applying the mercury salt may be adopted. Pieces of blotting-paper are damped with a stronger solution, and the print placed between the moistened sheets. This effects the same purpose, and renders the subsequent washing of the print less troublesome. The change which is seen to take place consists in a removal of the yellow tint generally seen in the whites of a faded print, and in

changing the blacks, which have generally lost warmth richness, and assumed a grey tint, to a much redder. This redness is sometimes carried so far as to seriously impair the beauty of the print, and this is one of the objections, we apprehend, to the process, which has stood in way of its adoption. This defect may, however, be rid of by a method we shall indicate presently. When solution of bichloride has done its office, the print should be thoroughly washed, and as the mercury salt is one readily soluble, considerable washing is necessary to effect its entire removal.

The other method of restoration consists in immersing the faded print in a neutral solution of chloride of gold, or, better still, of the chloride of gold and potassium chloride of gold and sodium. If the weather be cold solution may be very slightly warmed. The strength of the solution is not important, but if it be weak, the operation is slow. We have used a one-grain solution with advantage. The operation should be conducted in a light, and the print carefully watched. The yellow tint removed, and the whites and more delicate half-tones little bleached. If an ordinary commercial sample chloride of gold be used, without neutralizing, contain as it does, some traces of hydrochloric acid, considerable bleaching will take place, so seriously reducing the vigour of the print that the restoration of colour scarcely compensates for the loss of force.

Some attempts have been made to restore the faded image, when it has nearly disappeared, by development with gallic acid, but without success, some restoration of the image being more than compensated by the staining which generally results from the process. We recently received from a correspondent a request that we would "develop the latent image" on a piece of paper enclosed. On examination we found the supposed latent image to be an image faded, leaving only some faint yellow stains on a piece of albumenized paper. Our correspondent evidently thought—and, probably, not unnaturally—that the picture which the paper had once held was there still, only that it had become latent. The silver and gold of which the image had been formed were doubtless there, but by chemical change, assumed the form of colour salts. As we have said, one of the great wants in connection with the art is a method of restoring the image blackening again the metallic salts of which it consists. The search for a method is one well worthy of the efforts of the experimentalist, and will no doubt well repay the ceaseless discoverer of an efficient method.

ADIACTINIC GLASS FOR DARK ROOMS.

One of the difficulties experienced by the experimenter when working with extremely sensitive preparations arises from the sensitiveness of such preparations to traces of light in the dark room which had been found quite harmless when working the usual processes. This has been found especially the case in working with some of the more sensitive emulsions, which for with the usual yellow light employed in working wet plates. Two thicknesses of silver flashed orange glass will generally serve to protect the most sensitive plates; but where this fails a preparation supplied by Mr. Baily, which we noticed some time ago, may be tried. Mr. Baily has found a salt of chrysoidine, one of the aniline dyes, answer. He says:

"During the last two days in my studio, employing silver bromide for dry plate work, I have made use of white glass coloured by a preparation of aniline to light up my dark room. Among the numerous substances which I tried, one above all has in a high degree the property to arrest the active rays of light. This substance is named 'chrysoidine.' Chrysoidine is a crystalline substance, excessively rich in colouring matter, of a reddish yellowish appearance, soluble in water and alcohol, which facilitates its employment as a varnish to cover a pane

glass, or intermixed with gelatine in order to make a pliable film, or a stain or a dye in order to colour paper. To make a varnish it suffices to dissolve the powder in a varnish made with alcohol, leave it to cool, and then to filter it; it can then be employed as the ordinary varnish. Collodion with chrysoidine is prepared by replacing the alcohol by an alcoholic solution saturated with chrysoidine. The ether will precipitate a part of the product; it is, therefore, necessary to leave it a certain time to itself, and then to decant it with care. This preparation, poured upon a sheet of glass as collodion, gives a very intense colour, and replaces very advantageously yellow glass as employed at the present day. In some cases it is preferable to cover both sides of the glass with the varnish. One of the best means to utilise this product is to make pellicles of gelatine:—

White gelatine	300 grains
Water	1,900 "
Chrysoidine	40 "
Glycerine	46 "
Water containing 2 per cent. of alum	616 "

Begin by dissolving the chrysoidine in the 1,900 grains of hot water; filter, and allow it to cool. Proceed in the same manner as if you desired to make pellicular negatives by the method of M. Jeanseaud. It is necessary to have a pellicle as thick as possible, to obtain which, after having covered with talc and collodionized the glass, put a rim round it composed of soft wax. A kind of tray is thus obtained, into which the solution of gelatine is poured. The glass is now levelled, and the gelatine left to dry. When dry it is coated with a collodion containing castor oil. If the formula has been carefully followed a pellicle will be obtained of a ruby-red colour, which will arrest nearly the whole of the actinic rays of the spectrum.

"An excellent anti-photogenic paper can be made by impregnating a thickish white paper with a solution of—

Water	100 grains
Alcohol	2,300 "
Chrysoidine	47 "

The paper dyed in this solution can be employed to intercept the actinic rays from entering the dark room, for packing all substances liable to be spoiled by white light, such as dry plates, wet and dry emulsions, &c.

"A magnificent red dye named 'eosine' is equally soluble in water and alcohol, and can be employed in the same manner as chrysoidine; but as its power of colouring is inferior to the last-named substance, double the quantity must be employed."

A TOUR IN THURINGIA.

BY H. BADEN PRITCHARD.*

I FIND, as I proceed with my photographic work, that lookers-on are all impressed with one idea, that my apparatus is a plaything and nothing more. If I did not hold fast to camera and lens, and had not a companion to help me take care of the apparatus when I pull it out or put it away, bystanders would not have the least hesitation in good-humouredly overhauling it, so delighted are they, evidently, with the compactness and practicability of the whole affair.

A picture of the market-place at Eisenach, which I secure, with the old town hall at one corner and the grand ducal palace at the other, serves to gather round me half the inhabitants, whose only failing is that they are so overbearingly good-natured. Everything they do is done in a spirit of fun and good-will, and perhaps that is why I feel so annoyed with them at crowding round me. But I must say they are very good when the exposure begins, and, to show they know all about it, keep still as statues. Even the wooden-looking little soldier, with his

square-cut coat and spiky helmet, on guard before the palace, comes to a sudden standstill, and remains the while so stationary that he might have been made of lead.

But the good people want a reward for remaining quiet. "Now, I do pray you, tell me where I can get a copy of the photograph. I was standing right in the middle of the square, and kept perfectly still on purpose."

Even the item of the German army would come over and join his prayers to the others, only he dare not leave his post for fear the Grand Duke may be looking out of the window.

The old drawbridge and heavily-ironed gate of the Wartburg Castle make another good photograph, as also does the *Ritterhaus* to your right on entering, which remains exactly as it was when worthy Martin Luther found an asylum within its walls. The Luther rooms are intact and are shown to visitors—his bedstead, his arm-chair, his goodly flagon. On the walls are antique pictures of his parents and of the worthy doctor himself, but at one spot the plaster has been picked away, and the rough mortar is seen underneath. In this room it was that, when Luther was engaged in translating the Bible, the Evil One appeared to him as a tempter, and the reformer became so angry at the interruption that without more ado he threw the inkstand, ink and all, at the devil's head. The black stain upon the wall remained, we are told, for years, but now it has been removed bit by bit by relic-hunters, who have left the wall in the dilapidated state I have mentioned.

Martin Luther must have been a cheery, light-hearted, genial soul, one who took anything but a black view of the world.

"Who loves not woman, wine, and song,
Is but a fool his whole life long,"

was the substance of one little motto he wrote on the walls of his chamber; and his poems and hymns seem to tell far more of smiling nature, its warm sunshine, its bright green woods and chattering songsters, than of vaulted cell and cold penitentiary observances. For many months he was sheltered from harm by the grey old walls of the Wartburg, whose towers were simply impregnable in those days. No doubt whatever he had the Wartburg in his mind when he wrote the well-known hymn:

"Ein feste Burg ist unser Gott."

But it is not Luther alone who has made the Wartburg famous. It was here, exactly five hundred and seventy years ago, that the German bards or Minnesingers held a famous tournament, when the passion of the competitors waxed so high that it was decided the least successful should suffer death, a sentence which was not, however, carried out, on the intercession of the duchess.

The Wartburg, too, appears as one of the scenes in Wagner's opera of "Tannhauser," for the legend makes mention of the old burg; and the story of the Holy Elizabeth, who was once mistress of the castle, is yet better known. Elizabeth was the wife of the Landgrave of Thuringia, and her good deeds had made her beloved throughout the country. Her husband, however, looked coldly upon the merciful missions of his wife, and one day, returning from Eisenach, he met the Holy Elizabeth near a well at the foot of the burg, attended by her ladies, and carrying food and provisions in baskets to take down to the poor in the valley. Elizabeth, fearing the anger of her lord, at once covered her basket with a cloak. But he was not to be deceived.

"What have you there?" he cried passionately, tearing back her garment.

The basket stood revealed before him, but it was full, not of food, but of white roses.

The Elizabeth well is hidden away in the trees, and I have to search well before I find it. A roughly-wrought semi-circle in the rock, all moss-grown and worn by time, now marks the spot of the miracle, and at the foot of the

* Continued from page 440.

fountain are stone benches and a curiously carved font. No ray of sunlight penetrates through the dense beech boughs overhead, and, although I give an exposure of fully ten minutes, I hardly fear that I have secured a picture of the interesting retreat.

Behind the Wartburg is one dense mass of forest—a surging sea of leaves—and I descend into the valley once more to take views of a fairy dell I wot of. It is a narrow path in the wood between two precipitous rocky walls, so close at times that two people cannot well pass one another. It is the Annathal, and, where the path is so narrow, it is called the Dragon's Defile. Sometimes one can hardly see the narrow strip of blue sky overhead, so overgrown are the mossy rocks with clematis and greenery. Supreme quiet reigns in this cool, grotto-like retreat, whose walls sparkle with glistening drops of moisture, while here and there a recess full of moss and delicate ferns add their charms to the fairy abode. As you emerge into the beech-wood again, the air feels quite warm against your cheeks, and sweet forest odours come floating towards you.

You might pass day after day here gathering pretty pictures, for there is not a breath to quiver the delicate undergrowth, or bend the crimson fox-gloves, which are still blooming. A transparent green light, as the sun sheds its rays above, falls upon the scene, and it takes a good deal of resolution at last to pack up camera and dark slide and proceed on one's way.

I am afraid I shall have a trouble to develop some of my Warnerke tissue, for, although I give good exposures, most of them have been given in the dense woods where the only light is the green illumination that penetrates the trees. The season has not sufficiently advanced to give me autumn tints, and the dark greens, therefore, will have to be forced a bit on development to give me contrast. But I am not at all nervous as to the results of my labours, for in the Tyrol last year, when I carried the roller dark slide and flexible emulsion tissue for the first time, I was perfectly well satisfied with the results. These some of my readers may remember to have seen when I exhibited them at the Photographic Society in February last, together with a lot of other dry-plate productions.

I have now completed my first roll of tissue, and have consequently made upwards of thirty exposures. I have just changed my exposed roll for a fresh one I had in my portmanteau, which, with a little adhesive paper, is soon made fast to the rollers. The roll of exposed tissue I have enclosed in two or three thicknesses of red paper and taken to the post office, whence, for the sum of sevenpence halfpenny, I am assured it will be safely conveyed to my residence in England.

To-morrow I leave Eisenach to explore other portions of the forest near Schwarzburg, and will send you another letter in the course of next week.

ON A VERY SIMPLE WASHING TROUGH.

BY NELSON K. CHERRILL.

THE simple contrivance I am about to describe is one I have made for my own use, and will be found, I believe, as good as, or better than, many much more elaborate patterns. Should any of your readers think well of this, I should advise them to try one like it, as I am very fully satisfied with the work of mine.

The trough consists of a board some seven or eight feet in length, with two boards nailed on to the sides of it, the length being divided into a number of partitions, or cells, by pieces of wood, as shown in the cut. The drawing

shows the trough in section: the pieces A A A are about

three inches wide (i.e., high), and are nailed to the bottom of the trough; the pieces B B B are the same width, or, perhaps, a little wider, and are fixed right across from side to side, but so as to be quite clear of the bottom of the trough. The whole trough is placed at a slight angle, and the water simply runs in at one end from a tap, and out at the other into the drain.

It will be seen, on consideration of the cut, that the passage of the water through these little cells or divisions in the trough is on this wise. It enters at the upper side of the cell along the bottom of the trough, and runs over the top edge of the lower side of the cell into the well or division between A and B, whence it finds its way into the cell next below, and so on in through them all, entering each cell in turn at the bottom. Two or three stout pins stuck in the top of the dividing pieces A serve to prevent the prints being washed over into the wells, and so choking up the concern. I have provided a loose cover consisting of three pieces of braid, to keep out the dust, &c., as the trough is used out of doors.

I never place more than five or six prints in each cell or compartment, and I find that by being particular they do not stick together at the first; they get into the currents of the water as it flows, and keep on moving about all the time the trough is in action. I use as many of these troughs as are needed to take the prints done in the day's work, and I am quite confident that, in the morning, my prints are more free from hypo than they used to be when I washed them in a very ingenious but clumsy contrivance, with all sorts of water wheels and self-acting syphons and other complications.

It will be seen that in these troughs the water that washes the prints in first department or cell goes on to wash those in the next, and so on to the end; so that those in the lower part of the trough are washed in the washings of other prints. At first I thought this objectionable, but on careful consideration and experiment, I have proved that no mischief arises from this apparent shortcoming in the apparatus. I found, for instance, that a test solution being poured into the topmost box till it overflowed, and the water then being turned on, and the trough set in operation, the solution was carried through the trough, and expelled from all the cells, in less than ten minutes, so completely that not a trace of it could be found even in the last box.

I was induced to try some such plan of washing as I have here described from the exceedingly satisfactory results, as regards permanency, which I used to obtain when playing with photography as an amateur. I then washed the prints done in the day (perhaps two or three small views) in a saucer, under the tap in my father's back kitchen. Whether permanency depends upon washing, or not, I do not know; but I do know that the prints I washed in the manner described fifteen or sixteen years ago are as bright and good now as they were the day they were done.

I believe photographs (silver prints) done in this part of New Zealand are more permanent than is generally the case, and I can only trace the reason for this to the extraordinary purity of the water supply. There is not, I believe, another city in the world so well supplied with water. Every house has its own artesian well, and the water that comes up is so pure that you can make a nitrate bath with it without previous distillation, and that bath will work as well as any distilled water bath ever made.

A NOTE ON THE AERATION OF WATER.

BY NELSON K. CHERRILL.

It is said the trade of brewing can be only carried on with success in certain districts on account of its needing a peculiar quality in the water used. I should be sorry to

say that the effect produced on the processes of photography by the water used is so great in any case as absolutely to determine success or failure; but I am very sure that the quality of the water used has a great deal more to do with success and failure than many are prepared to admit.

The particular adverse quality in water I now speak of is "aeration," and a most peculiar quality it is. Much of the deep well (artesian) water in the South-East of England is so full of air-bells that a glass full of it will be found speckled all over with little air-bubbles if left standing for a few hours. These air-bubbles gradually increase in size till they become, in many cases, large enough to detach themselves and rise to the surface. In the two waters with which I am best acquainted in England—namely, those at Folkestone and Tunbridge Wells—this effect is so strongly developed that a glass plate left in a dish of water all night is, in the morning, covered on the under side with thousands of bubbles. With water of this class the greatest difficulty is found in avoiding failures in carbon printing, ceramic enamels, &c.

Let anyone whose practice of carbon printing shows a continual succession of small blisters, such as I see so much written about just now in the *News*, try this experiment:—Fill a deep dish with water from the tap, place in the bottom three stones or marbles, about half an inch in diameter, and on these lay a clean glass plate, so as to be about level and completely submerged. Let all this be done in the evening, and let all be left undisturbed till the following morning; then examine the glass very carefully, and notice if it be not covered on the under side with numerous small air-bells. If this be the case, let a second experiment be tried:—Take a piece of carbon tissue, and mount it in the usual way, with a squeegee, upon a piece of clean glass; when mounted, dry the glass and take it out of doors into the sunshine, and examine carefully the black surface of the tissue through the glass. If I err not, that surface will be found covered, more or less, with minute specks of clear silver lustre, quite invisible in the dim light of the dark room; but, when seen, sufficiently indicative of air-bells. These air-bells formed the greatest source of failure I have met with in working both the carbon and the enamel processes. In the one they "developed" with the print and marred its beauty, in the other they expanded in the heat of the muffle and split the film to a thousand pieces.

The only mechanical difficulty I met with in England, in doing the enamel process, was occasioned by this same splitting of the films. More than fifty per cent. of the enamels I did "split off" in the preliminary burning, and no process I could find would overcome the tendency, though at times it was much greater than at others. The water I am now using for photography has no tendency to aeration whatever. A glass plate left a week in it in the manner indicated above does not at any time show a single bubble, even when examined with a magnifying-glass. I fully determined this point long before I had any occasion to do enamels, having made up my mind that the splitting I referred to had been occasioned in the manner stated. I felt sure that it would not occur under my present circumstances. Acting upon this conviction, I threw the first enamel I made in Christ Church into the muffle in a manner which, at Tunbridge Wells, would have been looked upon as a conclusive proof of insanity; but the conjecture I had made was correct: no splitting of the film occurred, and I am now in a position to turn out enamels one after another without fear of failure.

There may be a moral in all this which will save some others from their troubles.

Cashel Street, Christ Church, New Zealand.

HEAT, LIGHT, AND ACTINISM.

We may apparently have heat without light, and light without heat. In the darkest room we cannot perceive vessels filled with boiling water, yet the warmth we experience on approaching them assures us that they are emitting radiations. Is not this heat without light? If we stand in the rays of the full moon, we cannot detect any increase of temperature. Is this not light without heat? It is true that in this latter instance we are mistaken as to the fact; but overlooking that—for the heat to be detected in the moonbeams requires the most sensitive apparatus—do not such observations assure us that heat and light are independent of each other, physical principles having an existence separate from each other?

Such were some of the arguments on which were sustained the hypothesis of the intrinsic difference of light and heat. In this no account was taken of the optical functions of the eye. Qualities were incorrectly attributed to radiations which, in truth, were due to peculiarities in the organ of vision.

The great service which the diffraction spectrum has rendered to science is the abolishment of all these imaginary independent existences—heat, light, actinism, &c.—and the substitution for them of the simpler conception of vibratory motions in the ether. The only difference existing among the radiations that issue from a grating, in the manner we have been describing, is in their wave lengths, or, what comes to the same thing, in their times of vibration. The diversity of effects produced depends on the quality of the surface on which they fall. If on a dark surface, and the more so in proportion to its blackness, they engender heat; if on the retina, they are interpreted by the mind as light; if on photographic preparations they produce decomposition, designated actinic effects.

Heat, light, actinism, are, then, not natural principles existing independently of each other, but effects arising in bodies from the reception of motions in the ether, motions which differ from each other in their rapidity. Of those that the eye can take cognizance of, the most rapid impart to the mind the sensation of violet light; the slowest, the sensation of red; and intermediate ones, the intermediate optical tints. Colours, like light itself, are nothing existing exteriorly. They are merely mental interpretations of modes of motion in the ether, and in this they represent musical sounds, which exist only as interpretations by the mind of waves in the air.—*Dr. John W. Draper, in Harper's Magazine for August.*

Correspondence.

PHOTOGRAPHY IN MELBOURNE.

DEAR SIR,—In the budget of *News* just handed to me on the arrival of the San Francisco Mail, I find the letter of your correspondent "Fife Atkinson," in which he comments rather severely upon my suggestion, made a year ago, in favour of the chances of a good operator in Melbourne.

I cannot suppose that the subject has much interest to your readers; at any rate, whatever interest it might have had at the moment, has passed, no doubt, ere this. Notwithstanding this, I must ask you to let me say a few words in reply. Corresponding at a three months' range between question asked and reply received, as we do between New Zealand and England, makes anything like a "discussion" quite out of the question. I will therefore reply as briefly as I can, and then let the matter drop.

Your correspondent takes exception to my suggestion on the ground that there are already thirty-seven photographers in Melbourne, and that most of these find it hard to "make both ends meet." Melbourne is a very large city.

I have no means of knowing the number of its inhabitants at the present time, but I find the population quoted in Haden's Dictionary of Dates as 100,000 in 1852. Supposing this to be correct, and also supposing that the population is not more now than then (a very unlikely supposition, I think) this would give, according to Mr. Atkinson's showing, about 2,700 souls in population to each photographer. This, I contend, is a large proportion. When I left Tunbridge Wells there were twelve or thirteen photographers in the district, containing less than 24,000 inhabitants. When I landed in this city there were twelve photographers among a population of only about 15,000, so that I do not think Melbourne is overrun yet with photographers. But your correspondent says those men can hardly "make both ends meet." Men have such different ideas upon this subject that it is hard to say much about it. A gentleman driving in a very nice "buggie" with a pair of horses was pointed out to me as one of the photographers whose name occurs in your correspondent's list. The photographers in Melbourne do not starve, any more than they do in other places, though perhaps none of them are making as much as they would like to make. Who does? I went into half a dozen of the studios in the city, and in all of them there was as much work going on as any one would expect to see in the middle of winter.

The impression I intended to convey in my letter, written just after my visit to Melbourne, was, that there was a good opening there for a really clever operator or two, who could introduce real novelties and improvements to the trade in the colony. There was, at the time I wrote, no one in the city doing either ceramic enamels, or carbon printing, or, as far as I could see, any of the beautiful and varied processes of opal printing, eburneum, mezz tint, Vander Weyde, &c. And if things are unchanged in the time since that was written, my opinion remains unchanged also.

All your readers must be aware that "things" are not very bright at present in any part of the world; trade seems depressed in most places; and when trade is low, photographers seem amongst the first to feel it. I have no means of knowing whether trade in general is better, or worse, in Melbourne, than when I wrote before.

Your correspondent mentions the case of one gentleman from England, who "set up" in Melbourne and failed lamentably, as a warning to all others who may be disposed to try in his steps. I do not know whether it is in very good taste to discuss the failure of this gentleman in the papers. He sailed from Melbourne a few days before I landed. I heard about him from dozens of people in the city (photographers and others), as there was much talk about it just at that time. All who spoke to me agreed in one statement, namely this: "He had plenty of work at the first." If this were the case, the failure was not attributable to want of support given by the Melbourne people to photographers, which is the point I wish to establish here.

One more word and I have done. Your correspondent says that there are only four photographers who keep any assistant at all in the way of operators, and that the wages of an operator average three pounds per week. According to this statement there are only about £12 per week paid out by the Melbourne photographers, all told, for the amount of skilled labour employed by them in the way of operators or skilled assistants. Does it look, I would ask, upon the face of it, that, if such be the case, a clever man would be able to make his way well there? That my friend who gave me the information as to what salaries were being paid to operators in Melbourne intentionally deceived me I will never for a moment believe, as he was a gentleman in a good position, and one from which he could gain no manner of advantage in misleading me, even had he wished to do so. Your correspondent gives the "lie direct" to my informant, but in so doing he has, as it seems to me, rather mended my case than spoiled it, for if among thirty-

seven photographers working among over 100,000 residents (many of whom are wealthy and almost all fairly well to do) there are, at present, only £12 per week paid out in wages to operators, it seems to me a "dead sure thing" that a really competent clever man, taking in a handful of novelties, would make way at once. My idea is, and always has been, that the fact of the work being done, makes the demand for it. I have always found it so. There is no demand for the good things of photography in Melbourne to-day, because the good things are not done there.—I am, sir, yours obediently, NELSON K. CHERRILL.

PS.—Since writing the above I am informed, but I cannot vouch for the truth of the information, that there are 175,000 inhabitants within three miles of the post office at Melbourne.

COLOURING PROCESSES FOR PHOTOGRAPHS.

SIR,—In your excellent leader upon this subject in the issue of September 7th, you very justly point out that the moment a transfer carbon process was invented by Mr. Swan, it was obvious that the gelatine image would lend itself to a certain style of artistic finish in colour, and this particular method of finish having been made the subject of one, if not more, patents recently obtained, we avail ourselves of the medium of your valuable journal to say a few words upon the subject. Whatever may have been the ideas of the original inventor of pigment printing, Mr. Swan, as to the applicability of colour to his invention, it is perfectly certain that his co worker and successor in the effort to render the invention commercially practicable, Mr. J. R. Johnson, was fully alive to the importance of the judicious application of colour to the back of the gelatinous carbon image.

Not only was this the case, but he showed that it was so by including the method for producing in colour most excellent results in his patent dated February 3rd, 1869, the following being his description of the *modus operandi* :—

"5. My fifth improvement consists in another mode of transferring the picture in one or many parts from its temporary to its permanent support for the purpose of being painted upon in oil or being varnished. I mount the picture in this case upon paper rendered transparent by wax, paraffin, or any fatty matters not fusible at the temperature used for developing the gelatine pigment prints. When the developed print is quite dry I varnish the surface of the permanent support which is to receive it, such as wood, panel, or oil canvas. I varnish also the face of the picture, and if of several parts, I carefully match these. The two varnished surfaces, when nearly dry, are then rubbed down together, and when in perfect contact the back of the waxed paper is warmed, and then leaves the pigment film perfectly attached to the panel or canvas. Before the picture is transferred it may be tinted or painted, and if painted with opaque colour it may be laid over another picture without the latter being seen. Thus I form composition pictures by laying down a landscape background, for example, upon the canvas, and upon it I place figures trimmed to their contours, and which have received a coating of white or coloured opaque varnish at the back. These then show as perfect forms without the landscape or other background interfering, and as the gelatine film is extremely thin the superposition is not visible."

Here, then, eight years ago, we have Mr. Johnson describing a method by which carbon prints are painted or tinted whilst still on their temporary support; after being treated with colour the picture is coated with a varnish, the permanent support being also varnished. The two surfaces are rubbed down together, and upon the removal of the temporary support the picture shows as a coloured work, the photograph in gelatine being imposed upon the colour behind it. To say the least of it, this is marvellously like the claim made by Monsieur Rousseau in his patent

dated October 24th, 1876, and printed in *extenso* by you last week.

There is yet another method of colouring photographs, producing very charming results, and which seems to be in danger of being claimed exclusively at the present moment. This method is well known, and has been extensively practised both in this country and in America. It formed the subject of a patent taken out so long ago as the 23rd of September, 1852, by M. Tardieu, who describes it as "Certain Improvements in the Colouring of Photographic Images." M. Tardieu says:—"The paper photograph, after being varnished, is mounted either on a frame or on a sheet of glass. Oil colours are preferred to be used; they are laid on at the back of the photograph thus rendered transparent, the transparency of the paper permitting the colours to appear in all their brightness on the paper side of the photographic image." In ignorance of this patent Mr. Duppa takes out a patent just one year later, in November, 1853, for "Improvements in Colouring Photographic Pictures." He thus describes his invention: "These improvements consist of rendering the front surface of photographs transparent with suitable varnish, and applying colours to the back surfaces, by which means the laying on of the colours will not require that artistic skill heretofore necessary, and results are obtained which cannot be obtained by the colouring on the front surface." He goes on to give full directions for rendering the paper translucent by means of wax, mastic, or other varnish, and given directions for colouring in oil.

In the same year a Monsieur Laverdet obtained provisional protection only for a method of colouring photographic pictures, "so as to give them a life-like or natural appearance, without impairing the exactitude of the photographic image, &c." He describes the method as rendering the photograph transparent "by coating the back with varnish, and causing it to penetrate the pores of the fabric containing the picture." When the varnish is dry, oil colours are laid on the back of the picture, "so as to imitate as closely as possible the natural tint of the object represented." Since that time patents have been taken out both in this country and America, notices have appeared in the journals and almanacs bearing upon cognate methods of colouring photographs, the gist of the whole matter being that the photographic image shall be superimposed upon the colour underneath.

As producers of coloured photographs by both of these methods, we think it expedient to clear the ground by calling the attention of your readers to what have been patented and published with respect to them, and also to secure to licensees any advantages there may be in methods published in the patents of THE AUTOTYPE COMPANY.

SOLAR CAMERA ENLARGEMENTS.

DEAR SIR,—Your leader of last week upon this subject conjured up a vision of bye-gone troubles that made such a vivid impression on me at the time that they will never be forgotten. 'Twas in the days of "Woodward's Solar Camera," and I, bursting with eagerness, invested what in those days was to me a very important sum. Alas! I found it was in an evil hour—the delays, the loss of time, the disappointment to customers, the worry and anxiety of that solar camera will never be forgotten by me. Prints on albumenized paper were produced now and then. Sometimes a bright sunny day would turn out a crop of respectable prints, but there were so few of them.

If anybody wants to know how few fine sunny days there are in a year, let him buy a solar camera. In this climate of ours the thing is absolutely impracticable. No doubt there are a few fine days upon which a certain amount of work could be done, but as a matter of business to a professional photographer, direct prints on paper or carbon tissue are, not to be done.

Again, a certain class of negative will do very well with a solar camera; but how about the dense ones or the thin ones? You have no control whatever over the result. If, on the contrary, you make your negatives from small positives—say albumen or carbon—you can achieve results which are impossible with the solar camera. For instance, you can "dodge" your positive in printing; you can retouch it, when it is printed, to any extent; you can put in shadows and detail where they are wanted. Then the enlarged negative is equally susceptible of treatment in the other direction. For landscape work you can combine skies with the most charming effect. And all this you can do with ordinary daylight, and in the depth of winter, and on the gloomiest of November days. The oxy-calcium light will be obedient to your will, and give you excellent results.

I think, Mr. Editor, you will see that, to say nothing of the absence of sunlight, which is in itself fatal to solar camera work in England, the balance of advantage is by far in favour of the enlarged negative process; and, as a very old and not unsuccessful practitioner, I hope you will allow me to say my say about solar camera enlargements.

MAGDUFF.

Talk in the Studio.

PHOTOGRAPHIC SOCIETY'S EXHIBITION.—In our advertising columns this week will be found particulars of the Society's Exhibition, to be inaugurated by a conversation, open to members and their friends, at 8 p.m., on Tuesday, October 9th. Special note should be taken by intending exhibitors of the condition that their pictures must be sent to 5, Pall Mall, not later than October 2nd.

CLOUD NEGATIVES.—We have received from Staff-Sergeant Perry some photographs illustrating the quality of the cloud negatives he is publishing. Practically, a good sky is the making of a picture, when in the absence of such a sky a mere diagram of the subject would have been presented, and we commend these sky negatives to our readers.

NOTE-BOOK FOR LANDSCAPE PHOTOGRAPHERS.—Every photographer who has spent a day or a few hours in the country with the camera has felt how much the interest of the pictures was increased by the preservation of a record of all the circumstances of their production. Messrs. Piper and Carter have just brought out a note-book for the preservation of such memoranda. Here are headings and columns for number, date, light, process, lens, stop, seconds, time of day, and general remarks, all under the general heading of the day "name of place." No recommendation from us is necessary to point out the advantages of such a note-book.

PHOTOGRAPHING PLANS OF PARIS.—"In compliance," says *Nature*, "with a suggestion from M. Engelhard, a member of the Municipal Council of Paris, the Prefect of the Seine has ordered photographs to be taken of every existing plan of the City of Paris, so that it will be possible to see all the series of transformations experienced by the city from the most remote period when such plans were made up to the present time."

A HORSE PHOTOGRAPHED AT FULL SPEED.—"Mr. Muybridge," says the *Daily Alta California*, "sends us a copy of an instantaneous photograph of 'Occident' taken when he was trotting at a speed of thirty-six feet per second, or a mile in two minutes and twenty-seven seconds. The negative was exposed to the light less than one-thousandth part of a second, so brief a time that the horse did not move a quarter of an inch. The photographer had made many experiments to secure the highest sensitiveness and the briefest possible exposure, and the result was a novelty in photographic art, and a delineation of speed which the eye cannot catch. At 2:27 the spokes of a sulky are invisible to the eye, as they spin around so fast that, taken separately, they are not distinguishable. The photograph shows each plainly, without blur. The negative was retouched before the photograph was printed, but we are assured that the outlines are unchanged; and we can well believe this, for much of the work has a character that

could scarcely be secured by hand. Mr. Muybridge intends to take a series of pictures, showing the step of 'Occident' at all its stages, and in this manner, for the first time, the precise differences in the motions of different horses can be clearly represented—a matter of much interest to horsemen, for trotters vary in their action, one having his fore leg straight when it touches the ground, another crooked, and so on. The following letter from Mr. Muybridge will be read with interest:—San Francisco, August 2nd, 1877. EDITORIAL ATTA.—When you did me the honour of asserting to Gov. Stanford your confidence in my ability to make a photograph of "Occident" while he was trotting at full speed—providing I could be induced to devote my attention to the subject—I will candidly admit I was perfectly amazed at the boldness and originality of your proposition. Having, however, given my patient devotion to the task the Governor imposed upon me, and instituted an exhaustive series of experiments with chemicals and apparatus, it affords me pleasure to submit to you a proof that your flattering confidence in the result of my endeavours was not altogether erroneous, and I herewith enclose you a photograph made from a negative which I believe to have been more rapidly executed than any ever made hitherto. The exposure was made while "Occident" was trotting past me at the rate of 2·27, accurately timed, or thirty-six feet in a second, about forty feet distant, the exposure of the negative being less than the one-thousandth part of a second. The length of exposure can be pretty accurately determined by the fact that the whip in the driver's hand did not move the distance of its diameter. The picture has been retouched, as is customary at this time with all first-class photographic work, for the purpose of giving a better effect to the details. In every other respect the photograph is exactly as it was made in the camera.—I am, yours faithfully,

"EDWARD J. MUYBRIDGE."

COMMENTS.—A cement for uniting metallic to non-metallic substances is composed of thin-made glue, mixed to the consistency of thick varnish with wood ashes. The ashes should be added gradually to the glue during ebullition, with constant stirring, and the cement should be used hot. A strong mucilage, capable of fastening wood or porcelain and glass together, is made of 8½ ounces of strong gum-arabic solution, to which a solution of 80 grains sulphate of aluminum dissolved in ½ ounce of water is added.—*Scientific American.*

To Correspondents.

J. BULLOCK.—We do not know of any efficient method of restoring the sensitiveness of old, rotten, insensitive collodion. The addition of zinc filings will remove the red colour, but it does not restore the sensitiveness. The only addition we have found as any good is a little bromide of cadmium. This improves matters, but it does not make the collodion equal to a sample in fairly good condition. The best purpose to which you can apply it is to add to new unripe collodion which has a repellent film, disposing it to matt silver stains, or to fog. It is often useful for this purpose, and also for cleaning plates.

J. T. D.—We do not know of anyone who supplies the class of pictures you mention of cards of any class at the rate of 4s. a gross. It is possible that some of the photo-mechanical prints used for decorative purposes may be possibly supplied at such rates; but we do not know the producers. We cannot see that it would be possible to supply silver prints card size at the rate of fourpence per dozen.

H. B. (Peckham Rye).—We fear that we cannot give advice of much practical value, except so far as it may be cautionary. It is difficult to make photography profitable without giving yourself up to it, and practising it as a trade. So far as we have been able to observe, it is difficult to make it profitable if practised as an amateur. Portrait photography is, as a rule, the most profitable branch, and the most easy to acquire a connection in; but you must be prepared to work for the public when they desire it, not simply when you choose. Landscape work would be most easy to undertake as an amateur; but it requires very good work, and, if possible, some speciality of subject or treatment to find a market for landscapes. If you have examples of your work, call on Messrs. Marion and Co., of Soho Square, who are large publishers of photographs, and ascertain from them if your pictures are likely to sell, or if they will undertake to publish them.

C. SMITH.—Your lens must indeed be bad if the bad definition is not improved by a stop. It is bad for even a "common French one," as you describe it. Get rid of it at once, and get another, bearing in mind that a low price does not always include cheapness. Get one, if possible, by one of the good English makers. If your finances are limited, you may get a good one second-hand at a reasonable price.

ENTHUSIAST.—It is somewhat difficult to convey in words the exact depth to print before toning. The rule is to print a little deeper than you wish the finished print to appear. Experience is the best guide, and that is soon acquired. Bear in mind, however, that there is a difference in baths as to the extent to which they bleach or reduce the depth of the print. A new gold bath generally reduces more than an old one, and some baths scarcely reduce at all. There is sometimes also a difference in the extent to which different samples lose depth in toning and fixing. Observation here is your only guide.

G. E. WALES.—We regret that we do not see how we can efficiently help you. We publish a process by which others produce very charming pictures with very short exposure. You try the same process, and state that you are careful to follow instructions, but you fail to get anything but a very poor negative with very long exposure. We can only come to the conclusion that you deviate in some way from the instructions; but it is impossible for us to tell in what point. The possibility of your coffee being adulterated with chicory is doubtless a circumstance of note. Get coffee berries and grind them yourself, and try again with greater care and precision.

FRED WARNER.—There is no method of restoring a distempered background except recolouring it; and unless the colour already there have been well fixed with size, it is in danger of working up. It may be well to treat it first with a good size of glue, applied warm. Then mix a grey tint, using whitening reduced to the proper colour by the addition of black or brown umber and a proper quantity of size. Apply gently with a large brush; but remember that distemper colours require considerable skill to apply quite evenly.

NONPLUSSED.—The dirty, yellow, 'spotty, and mottled effect of your prints is due to imperfect fixation. This may arise from the use of an old exhausted fixing bath; or from a very weak fixing bath; or from too short immersion; or from the prints sticking together and not getting properly in contact with the fixing solution. A hypo. bath should never be used for more than one batch of prints. It should consist of hypo one part, to water four or five parts, and the print should be immersed for about fifteen minutes, and kept moving, so that it is thoroughly exposed to the action of the solution. 2. Oyster-shell markings are almost invariably due to one cause; namely, the use of a horny repellent collodion. When the collodion is a little older the tendency will disappear. Adding a drop or two of distilled water to each ounce of collodion, and shaking well, will sometimes effect an improvement. Immersing the bath before it is too well set is a good thing. Keep the inner frames quite clean, and place wet blotting-paper at the back of the plate. Always develop as soon as possible after the plate has left the silver bath. If you have a little of an old somewhat rotten sample of collodion to add to that in use, it will improve matters.

FRANK BUSHNELL.—An assistant may become a member of the Photographic Society.

BROMO.—We have not ourselves made comparative trials; but so far as our information goes, B is undoubtedly preferable in all points.

HOWARD W. ANDREWS.—The film dissolving on being varnished is due to the quality of the collodion. Some samples when new, and others as they grow old, have the quality of being soluble in alcohol, of which the varnish is made. The remedy is to give the film a coating of gum, gelatine, or albumen, very dilute, and drying before applying the varnish. The albumen or other coating may be applied to the wet negative before drying. Write to the gentleman in question and ask: we do not know of any other way.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.
A PHOTOGRAPHER IN LUCK—PRIVILEGES OF PHOTOGRAPHERS
IN FRANCE.

A Photographer in Luck.—Photographers, like everybody else in this world, have their good and bad luck; and when they do get a stroke of good fortune it usually springs from very little. A travelling photographer, a few days ago, making a tour around Paris, came to Saint Germain, and began work in the place with his modest apparatus and appliances. Country operators of this class usually understand business, and generally succeed when they make application. Perhaps it is a pony-carriage just starting off to give the young ones an airing, and Paterfamilias is only too delighted when the stranger comes up and proposes to take a picture of the group then and there. Or, may be, there is a tennis party on the lawn, or afternoon tea going on *à la française*, and under these circumstances the travelling photographer is sure to be welcome when he makes his application. The whole matter is treated as a joke—as a good bit of fun—by those interested, but they are not on that account less anxious about the result. The photographer, if he is a plausible man and well up to his work, makes a very good thing of it in the end, for the chances are he secures a very charming little picture indeed. There has been no preparation, no fuss about the affair, and the photographer has made his appearance just at the nick of time. Everybody is delighted, and none less, probably, than the photographer himself. In the instance to which we have alluded, the photographer on the look-out for work not unnaturally proceeded to the pretty villas, of which so many abound in the suburb of St. Germain, and in time came to the Pavillon Henry IV., on the terrace of which was an old gentleman walking briskly to and fro for his morning constitutional. He was picturesquely clad, with a big muffler round his neck, his round, chubby face, though somewhat lined and furrowed, being still ruddy with health, while a pair of bright eyes, not a bit impaired by age, looked sharply through a pair of spectacles. The gentleman had a kindly, good humoured expression, and the photographer had no hesitation, therefore, in asking to be allowed to take a portrait, with the terrace as a suitable foreground. Camera and plate were ready in a trice, and the old gentleman posed himself without more ado, the result being a very characteristic portrait and a good picture. Next day, before our friend had time hardly to print a proof for his patron, the latter died, and France had lost its grandest politician, the first President of the Republic, the liberator of its territory. M. Thiers had died suddenly, and the photographer's last picture of the great statesman bide fair to realise a small fortune. It is a carte picture, and is priced at two francs, and is said to have enjoyed an enormous sale on the day of the funeral and subsequently. It is this photograph which was reproduced by the *Illustrated London News* a fortnight since, and which many of our readers have doubtless seen. It represents the octogenarian ex-minister hale and hearty, and apparently in sound health, on the terrace of the Pavillon Henri IV.; and fortunate, indeed, are our Gallic neighbours to have so striking a likeness of their beloved first president. A picture was also taken, with the camera, of the deceased lying in state in the chamber of death; but this, though of interest to many, does not, as a matter of course, command the great sale which has attended the little carte-de-visite photograph of the travelling operator.

Privileges of Photographers in France.—The French Government evidently does not mean to take half measures in regard to the regulations it recently issued for photographing the State collections in museums and galleries. Further particulars are now announced, and the direction of affairs has been given over to a well-appointed Commission, among whom are to be found the names of MM. Davanne, Almon-Girard, and St. Clare-Deville. To this

Commission will be entrusted the consideration of all questions likely to arise, and all applications made by photographers and others to avail themselves of the privileges just accorded. These consist, our readers may remember, of permission to take photographs at all public galleries throughout France, on one condition—that the use of dry plates is strictly adhered to. Hitherto, it is said, the refusal to admit photographers to the galleries was based upon the supposition that they might injure the apartments with their chemicals, or inconvenience the general public with their apparatus, &c. But now that dry plates have arrived at such a state of perfection there is no reason any longer for the photographer to bring anything with him but camera and plates, and the spilling of liquids is an impossibility, since no operation beyond those of focussing and exposing are to be performed inside the building, except under very special and exceptional circumstances. To meet the latter contingency some of the galleries are to be fitted with laboratory and dark room, where work may be conducted with every facility; but it will be only privileged individuals who will be permitted to use the appliances. It will be a long time, we expect, before the authorities of the British Museum, National Gallery, and Royal Academy accord such privileges to British photographers, or that a photographic studio will be erected in some handy corridor near the galleries. In France the regulations are briefly these. The photographer makes application to reproduce this or that picture or object of interest, and gives his reasons why such reproduction is really called for. If the application is a *bona fide* one, and reasonable—for some discretion must naturally be exercised—the photographer is informed that his request is granted, and that if he gives an undertaking to conform to the regulations, he may commence work at once. In return for the privilege accorded him, he must deposit with the Commission a duplicate negative of everything he takes, together with a couple of prints, and these negatives and pictures become the absolute property of the State. They are taken in charge by the Commission, and by it sent to a central photographic establishment, where they are preserved or printed as may be deemed necessary. This central photographic establishment has, however, other duties to perform beyond that of printing and registering the negatives it receives from those who work in the galleries. Its officers are to superintend and overlook any photographic operations undertaken in State buildings by private photographers, and are, moreover, to furnish instruction to those who may be engaged in Government work. Thus when the State undertakes, as in the case of the recent Transit of Venus observations, to make records of its own, instead of instruction being given in private studios, it will be imparted in the central photographic laboratory of the State, where the pupils will have every facility given them for practice and study. And when we bear in mind that such instruction will be imparted under the auspices of such men as Davanne and others whom we have mentioned, it certainly goes without saying that every scientific improvement and novelty will have due attention. To-day, more than ever, do we require the aid of scientific men to help us on, and to guide us safely through the difficulties and obstacles that beset, in a greater or less degree, the carbon process, the emulsion process, and other methods that are rapidly serving to perfect photography. We trust that beyond its other duties the central State laboratory may do something towards undertaking scientific investigation and research with a view to the progress of our art.

M. DAVANNE ON EMULSION PROCESS.*

By reason of the success and incontestable advantages presented by the emulsion process, I think it may be

* *Bulletin de la Société Française.*

interesting just now to point out some faults that may arise from impatience, inexperience, or, by chance, in the preparation and treatment of the plates. Such defects I myself have met with, and have sought to overcome by various means.

Granted the employment of good materials, it has nevertheless happened to me, in sensitizing the bromized collodion, and in the production of the emulsion to obtain the formation of a partial precipitate of bromide of silver, giving a pasty emulsion of bad appearance and bad qualities, instead of a product presenting, by transparency, the orange colour which is the indication of the molecular division which it is sought to bring about. This result was due, no doubt, to my impatience, which caused me to add too rapidly the alcoholic solution of nitrate of silver to the bromized collodion, M. Chardon telling us explicitly that the addition should be made by degrees, and with a good deal of agitation. I got over the difficulty, as M. Andra has pointed out, by pouring the bromized collodion into the nitrated alcohol; but being, perhaps, rather too sparing of my labour, I did not agitate enough to obtain perfect division.

I then had an apparatus of this kind constructed, which gave me very good results.

I make my solution of nitrate of silver in alcohol in a glass bulb which is stoppered by a perforated cork. Into the perforation is put a glass tube, which protrudes from the cork some four or five centimetres. Inside the bulb the tube is flush with the cork, and the latter is of such a length that, when the bulb is turned upside down, the cork, E, is capable of fitting into the mouth of a bottle. The end of a glass tube, which protrudes, is drawn to a thread. When the bulb has been mounted by means of the cork, upon the bottle, the only means of communication is through the finely-drawn tube, and the atmospheric pressure does not allow the liquid from the bulb to fall unless a vigorous shaking takes place. Every time the apparatus is agitated, a little of the alcoholic solution of nitrate falls, and in this way the emulsion is formed little by little under the best conditions. In my former operations, emulsion I made deposited more or less bromide of silver in a few hours, while that now produced in the manner indicated, if allowed to stand four-and-twenty hours, shows no trace of deposition, so finely divided are the particles.

The formation of pasty bromide of silver is the principal cause, although not only the only one, of the matt, porcelain appearance assumed by emulsion plates on drying. Such plates are not altogether bad, for good results may be secured with matt films. At the same time an inspection with the magnifier shows a more decided grain than that of plates having a polished surface.

In the experiments I made, the same emulsion which gave me matt surfaces was also competent to give me brilliant films. It was only necessary to let the pro-

duct remain for twenty-four hours. The pasty—or rather chalky—bromide of silver is precipitated to the bottom of the bottle, while the very finely divided compound remains in suspension, and by means of a simple decantation, followed by filtration through cotton-wool, I have obtained surfaces as brilliant almost as albumenized collodion. But in this case the film became impoverished; its sensitiveness remained about the same; but on development there was an absence of vigour in the impression, and when it came to pushing the alkaline development, the picture seemed to become weaker rather than stronger. This last effect is due, not to a diminution in the vigour of the blacks of the negative, but rather to a fog, which, on development, is produced in the clear parts, and which tends to render the whole surface universally covered with a silver deposit.

A very simple method of obtaining, in these circumstances, the necessary vigour, consists in following the alkaline development with an acid development, an operation well known to all. As soon as the image is seen in all its details after treatment with alkaline solution, it is washed with water, and then there is poured upon it:—

Water	1,000 cub. cents.
Gallic acid	3 grammes
Pyrogallic acid	3 "
Crystallized acetic acid	15 cub. cents.

The acid saturates every trace of alkali still remaining after washing, and the former is then poured back into the developing cup, a little nitrate of silver solution of three per cent. strength being added; this mixture is poured over the plate again, and the same closely watched as it waxes in intensity, until at last there is produced a very thin image, but possessed of brilliancy and sufficient vigour.

I may remark here that it is well, if not actually indispensable, to wash the surface of the plate with alcohol before proceeding to development; the difference in sensitiveness may be estimated probably at a hundred per cent. A pose of thirty seconds was found amply sufficient with a lens with small diaphragm when development was preceded with washing by alcohol, while I could scarcely obtain the same result with a minute's exposure when I did not flow the film first of all with alcohol.

The alcohol, dissolving the quinine, renders the film at once more permeable, and allows a deeper action of the reagent when these are applied, and this accounts for the greater sensitiveness exhibited. The application of the alcohol, although but an accessory, should be done with care, for if the quinine does not dissolve equally, or if it is again precipitated on washing, because the alcohol would be saturated, or if the plate still maintains its greasy appearance, the contact of the developer will not be uniform, and patches or inequalities will arise, which will militate against the purity of the image.

Finally, it must not be taken for granted that emulsions which have been exposed to light are of no value. It is neither wise nor economical to throw away such as do not give good results. Experience has proved to me that an excellent use may be made of these products, of which I had at one time very nearly a litre, the result of many experiments. Applying the principle that in the presence of soluble bromides or iodides the bromide and iodide of silver have no sensitiveness, and that they lose even under the influence of light the action which the latter would produce if the salts were sensitive, I added to my bottle of residues a few cubic centimetres of bromized collodion, and to be more sure about annulling all previous action of light, I put in a drop of pure bromine for every one hundred cubic centimetres of liquid, the drops being first of all dissolved in a little alcohol. I exposed the whole in the open air, and after a repose of some hours I decanted the emulsion, and precipitated it with hot water. The product, when dry, and treated like other emulsions, gave me very good results.

THE DISCOVERER OF TALBOTYPE.*

MR. W. H. FOX TALBOT, F.R.S., of Laycock Abbey, Wiltshire, whose death was recorded in our columns on Friday, as having happened on Monday, September 17, at his country residence, at the age of seventy-seven, was the eldest son of the late Mr. William Davenport Talbot, by his marriage with Lady Elizabeth Theresa Fox-Strangeways, eldest daughter of Henry Thomas, second Earl of Ilchester. He was born in February, 1800, and received his early education at Harrow, then under Dr. Butler, afterwards Dean of Peterborough, the father of the present head master. In due course of time he was removed to Trinity College, Cambridge, where he gained the Porson Prize for Greek Iambic verse in 1820, and took his degree in the following year as Chancellor's Medallist.

He does not appear to have been called to the bar, or in fact to have followed any learned profession; but he took a delight in chemistry and in chemical experiments, with which he combined a zeal for archæology and antiquarian studies. Elected as a Liberal for the borough of Chippenham at the general election which followed on the passing of the first Reform Bill, he held his seat for two years, but then withdrew from political life. His motives for so doing we can gather from his own writings. Mr. Talbot tells us, in his "Pencil of Nature," that in the month of October, 1833, when trying to sketch the scenery along the shores of the lake of Como, by the aid of a camera-lucida, and wearied by many successive failures, he was "led to reflect on the inimitable beauty of the pictures painted by the hand of nature, pictures which the glass lens of the camera throws upon the paper in its focus," and further "to consider whether it would be possible to make these pictures permanent." He was aware that paper might, by chemical means, be made sensitive to the action of light, and he resolved to try and follow up the idea by experiments. By a long and elaborate course of these experiments, which it would be useless now to enumerate in detail, he had nearly arrived at a result satisfactory to himself, when he read one day in a scientific journal that his own solution of the mystery had been, if not anticipated, at all events rivalled, by the parallel researches of M. Daguerre. To use his own words, "An event occurred in the scientific world which in some degree frustrated the hope with which I had pursued during nearly five years this long and complicated but interesting series of experiments—the hope, namely, of being able to announce to the world the existence of the new art, which has since been named photography." This was, of course, the publication of an account in January, 1839, by M. Daguerre of what was termed the Daguerreotype process after its discovery. Mr. Talbot lost no time in communicating to the Royal Society the details of his own independent process, which he called at first photogenic drawing, and afterwards calotype. Sir David Brewster, however, perceived at once its value and importance, and therefore proposed that it should be called Talbotype—and the name was to some extent adopted, until, with the full consent of its modest discoverer, it became popularly merged in the more comprehensive term of photography.

The two rival processes, though one in their design and object, differ very largely in matter of detail. As a writer in the *English Encyclopædia* observes:—

"In Daguerre's process the image was produced upon metal plates; in that of Mr. Talbot the same image was obtained upon paper, and neither the one nor the other could claim to be the first who had obtained sun-pictures upon a surface previously rendered sensitive, the principle having been perceived and announced by Thomas Wedgwood in his 'Account of the Method of Copying Paintings upon Glass, with Observations by Sir Humphrey Davy,' which was published in the 'Transactions' of the British

Institution as far back as 1802, and later by M. Niépce, who had made known in London in 1827 his own experiments in obtaining sun-pictures. But in none of these was the image either distinct or permanent; so that M. Daguerre and Mr. Talbot were the first to apply the principle practically, and from them the photographic art may be said to date its origin. It is probable that this statement does justice to all who were concerned in this discovery, both theoretically and in the application of theory to practice."

Mr. Talbot's invention, however, remained for some months in a very imperfect state; and it was not till the autumn of 1840 that he made the discovery which "laid the foundation of the photographic art in its present form"—namely, that sensitive paper, during the first few seconds of its exposure to the light, receives an invisible image perfect in all respects, and that, in order to render the image visible, it is sufficient to wash the paper over with gallic acid, or with some other astringent liquid. In 1842 Mr. Talbot was presented with the gold medal of the Royal Society in recognition of the part which he had taken in the discovery of photography. Already—namely, in 1841—he had taken the necessary steps for securing to himself, by patent the commercial profits which were likely to accrue from this novel use of the sun's rays; but upon second thoughts, and becoming convinced of the various public and private uses to which the art might be made subservient, and at the request of several members of the Royal Society, he consented to forego the profitable privilege, and to throw open to the public his discovery, with what results is known now to all the world, with one single reservation—that of taking portraits. This, however, he afterwards waived, the legal question having been raised, and somewhat unsatisfactorily decided, in one of the superior courts.

In 1851 Mr. Fox Talbot presented to the Royal Society, and also to the Académie des Sciences at Paris, an account of sundry further experiments which he had made in the direction of obtaining instantaneous photographs; and two years later he published a notice of some successful experiments in the application of photography to the work of engraving on steel plates.

Of late years Mr. Fox Talbot employed much of his time in the study of languages, and especially in the work of deciphering the cuneiform inscriptions on Assyrian monuments. He was also the author of several valuable works, such as "The Pencil of Nature," quoted above; "Legendary Tales;" "Hermes, or Classical and Antiquarian Researches;" "New Arguments of the Antiquity of the Book of Genesis," and "English Etymologies." He also contributed largely to the papers read at meetings of the Society of Biblical Archæology, and of other learned Societies.

Mr. Fox Talbot married in 1832 Constance, youngest daughter of the late Mr. Francis Mundy, of Markeaton, Derbyshire, by whom he has left a family to lament his loss.—

A GLANCE AT PHOTOMETERS.*

ARITHMETICAL PHOTOMETER.

To carbon workers, the very first thing needed is a photometer—a photometer in every way reliable and trustworthy—as a certain and sure guide in printing, for nothing can be known of the pigment picture until it is developed. Then a glance tells the story of failure or success. If under-exposed, there is no help for it; if not much over-exposed, we are often told that hotter water will bring it down. This it will do, but the harmony is destroyed, and no one who works conscientiously, or is careful of his reputation, will turn out such pictures. The carbon process is a very exacting one in almost all of

* *The Times*.* *St. Louis Practical Photographer*.

its details of manipulation, and in nothing more so than in precise and exact exposure. Anything less or more than "just right" is failure: and after a practice of ten years in pigment printing, I have never found a remedy for either defect which I can conscientiously introduce to the photographic brotherhood. There are many ways of reducing an over-exposed print, as almost all are aware of; but, as I before said, this is only accomplished at the expense of the harmony of the picture. So that it would seem from the foregoing that exactness of exposure is imperative. And so it is.

A great bar in the way of hitting off just the right exposure is the photometers commonly used, which are little better than guess work, and are the cause of uncertainty, and consequent failure, waste of precious time and costly material.

During the past five years I have made and used photometers to regulate the exposures in pigment printing on various principles as proposed in the different photographic publications from time to time. I have tried all that have come under my notice, with the single exception, perhaps, of the one named to me to be the best.

WILLIAM HENRY FOX TALBOT, F.R.S.

It is somewhat difficult to realize that an art which has taken such deep root in almost every department of art, science, and industry—in aiding research and investigation, in easily and rapidly producing unchallengeable records, superseding largely painting, engraving, and lithography—is still so young that many of its progenitors are still alive. The actual inventor of photography has just died. A couple of lines in the Obituary of the *Times* of Saturday last briefly announces: "On the 17th inst., at Lacock Abbey, Wilt., William Henry Fox Talbot, Esq., F.R.S., in his seventy-eighth year." Experiments in delineating objects by the action of light on substances sensitive to its chemical action had been made before by various persons. Wedgwood and Davy had been in some degree successful. Niepce had been still more so, but not sufficiently to give a practical process to the world. But Talbot, contemporary with Daguerre, and slightly preceding him in a detailed announcement of his method, invented a practical process of sun drawing, a development of which is in practice in the present day.

William Henry Fox Talbot was of patrician descent, being descended on the maternal side from the Earls of Shrewsbury. He was the son of W. D. Talbot, of Lacock Abbey, in Wiltshire. He received his education in boyhood at Harrow School, and subsequently graduated at Trinity College, Cambridge, where he won two university prizes. In the first reformed Parliament Mr. Fox Talbot sat as member for Chippenham. Politics did not, however, entirely absorb his attention, for within a couple of years, in 1834, we find him making his first experiments with the chemical action of light, which in the course of a few years brought forth very definite results. On the 31st of January, 1839, he read a paper before the Royal Society on what he then termed "Photogenic Drawing." The operation consisted in treating writing-paper with a solution of common salt, and subsequently with a solution of nitrate of silver, forming, by the now well understood reaction, chloride of silver, on the surface of the paper. Lace, leaves, ferns, and similar objects laid upon this paper, and the whole then submitted to light, produced white images of the objects, which served as negatives on a dark ground produced by the action of light on the uncovered surface. This facsimile was so marvellously accurate that it excited universal admiration, and its simplicity, ease, and rapidity were regarded as marvellous. A copy which, as the paper which appears in the "Transactions" of the Society remarks, "would take the most skilful artist days or weeks of labour to trace or copy, is effected by the boundless powers of natural chemistry in the space of a few seconds."

thirty-two minutes, No. 6 in sixty-four, and No. 10 in eight to show the theory of a perfect exposure.

Now, the above-described thing like this. The number of the numbers increase with proportion, as shown in the O.C.D., and I may say here from data obtained from experiment and verified, made against a photometer which never will give the directions to a

On the vertical line to the of exposure of the different equal parts. From these lines are projected, and a line from the photometer points through which the which of the year 1841 he haducing camera impressions, could be printed by his method.

method, which he patented, was a type—a complete and perfect process, the analogue of the photography day. In this process iodide of silver was used, and gallic acid the developing agent. The collotype process was largely practised by the photographic amateurs, and, in skilled hands, produced perfect results as we have seen by any other method, notwithstanding the great advances which have been made in the art. The use of paper for negative superseded, however, by collodion in 1852. Shortly after this Mr. Talbot was sufficiently ill advised to bring an action for infringement of his patent against a photographer using the collodion process, on the score that the film of iodized collodion was the equivalent of a film of iodized paper. In this attempt, however, he failed, in the great trial Talbot v. Laroche, decided in favour of the defendant. It is right to add here that in 1852 Mr. Talbot made a present of his process to the public, reserving patent rights only in its application to professional portraiture. He had previously given permission to use his patented process to a few amateurs, whose skilful labours not only gave credit to the process, but helped to perfect it. Chief among these was Dr. Diamond, one of the earliest and most successful amongst collotypists.

Some of the earliest steps in photo-engraving are due to Mr. Talbot. In 1853 he patented a process of photographic etching or engraving. In this process a steel plate which was coated with a film of mated gelatine, which was exposed under a cliché subsequently etching with a solution of bichloride of platinum. In working this process, which was suitable for subjects in black and white, Mr. Talbot endeavoured to secure gradation by the use of first employed what he termed beds, to give more grain or texture. The subject of photo-engraving continued to engage his attention, and he made further improvements, by which he succeeded in obtaining promising results, but not sufficiently perfect to give the process a commercial standing. About the same time Talbot gave much attention to perfecting an albumen process on porcelain tablets, which he patented. This was, under some conditions, very sensitive, and gave in the fraction of a second.

Mr. Fox Talbot has not recently maintained his interest in photography very actively. He never associated with photographic investigators, and never joined the Photographic Society. He was, however, an honorary member a few years ago, as a recognition of his claims in connection with the art. Of late years he devoted himself more to antiquarian researches,

consisting of the adjustable slit and the collimating lens; 3rd. The prisms; and, 4th. The camera with its lens.

The starting-point from which to commence procuring apparatus is undoubtedly the collimator, as on it depend the dimensions of the rest of the apparatus. It need scarcely be said that those who possess a spectroscope (not a direct vision one) will find the prisms of suitable dimensions for the collimator, but for those who desire to undertake the work without spending £50 or £60 on it, I recommend that the apparatus be purchased singly, and without being fitted up with micrometers, &c., in an expensive manner, since all this elaboration for photographic work is practically useless.

The collimator for good work should not be less than eighteen inches in length, and the collimating lens should be about $1\frac{1}{2}$ inches in diameter. The slit should be the most perfect of its kind, as on its accuracy depends in a great measure the quality of the resulting photographs. It should close perfectly through its whole length, and it is advisable that its jaws should approximate to knife-edges, since, if thicker, it is possible, and probable, that the image of the slit which gives the absorption (or bright) lines of the spectrum may at one time be formed by the inner part of the slit, and at another by the outer, a proceeding which is detrimental to sharp definition. The outer margin of the collimating lens should not be employed, and if the spot of light (when the light is thrown by the condenser on the slit) occupy a diameter of about one inch, that is the utmost that should be utilized. Diaphragms in the interior of the collimating tube should be arranged to effect this, and also to prevent light reflected from the sides of the tube reaching the lens. The section of a collimator is given in the

figure. The slit should be attached to an inner drawer tube, as shown.

In the ordinary spectroscope the collimator is attached to the iron or brass base which bears the prisms, and is, as a rule, only attached at the end near the lens by a socket and screw arrangement. Unless the workmanship be first-rate there is a danger of vibration by such an attachment. If the tube be supported in a cradle, however, the danger vanishes. For my collimator I have had made a wood cradle of the following shape. At one end are two screws

by which alteration in the height of the respective ends can be made, and a single screw at the other. By these three screws we have a perfect bearing on any surface, and a means of elevating the collimator bodily, or of altering it in inclination. The shape of the cradle itself also causes the tube to take a perfect bearing. The only thing wanting is to secure exact perpendicularity of the slit, and, practically, this is better done by hand than by any screw arrangement.

This cradle can be easily made by the merest tyro in carpentry, and answers its purpose as well as any much more expensive piece of apparatus. I may add that if greater firmness be required than that given by the weight of the collimator itself, it is easy to weight the base with lead, and to furnish the top of the Y's with a spring to clamp the tube into its place as in an ordinary theodolite. In regard to the lens of the collimator it is better that it should be achromatic, but this is not absolutely essential. For some time, and for a fixed purpose, I used a simple quartz lens. This caused a slight difficulty in focussing

parts of the spectrum, but not an insurmountable one. It will be found that in using an achromatic the difference in length of focus of the different rays is not exaggerated, as it is when an uncorrected lens is employed.

Having fixed on the collimator, the next piece of apparatus to be procured is a condenser. The image of the sun formed by it on the slit should entirely fill it, and it will be found that a pleasant dimension for the breadth of the spectrum is about three-quarters of an inch; in which case, supposing a six-foot camera be used, a convenient focal length for the condenser will be about three feet; that is, it will form an image of the sun about three-tenths of an inch in diameter. Supposing we fix on three feet as the focal length, and the available aperture of the collimating lens to be one inch, and its length eighteen inches, this at once fixes the maximum diameter of the condenser. It should just illuminate the one-inch, and no more. This would give it a diameter of two inches. If it be an achromatic lens, so much the better; but a common plano-convex or double convex lens will answer. And if the diameter be greater than two inches, a diaphragm must be used to get it down to that diameter.

The annexed figure shows a convenient mounting for

the condenser, being adjustable as to height, and by means of screws fixed in the base-board is made adjustable as to inclination of the axis of the lens to the vertical.

(To be continued.)

A TOUR IN THURINGIA.

BY H. BADEN PRITCHARD.*

ALTHOUGH Thuringia is not an extensive district, you cannot journey a dozen miles in one direction or the other without leaving one principality and entering another. A walk the first day, and a carriage drive the next, brought me through three different little dukedoms, while the territory upon which I now stand, called Schwarzburg-Rudolstadt, belongs, it appears, to somebody who is neither a duke nor a grand-duke, but only a prince. Of course he lives in a palace, but then all princes do that, and he goes out hunting every day of the week, for there is nothing else to do. He has an army, I know, because I met him just outside the courtyard.

"His Transparency does not permit any one to enter the courtyard," said the army to me, as I was walking towards the palace. He was a very nice little soldier indeed, and, as I did not want to get him into trouble, I at once complied with his request.

I thought, however, that his Transparency would not mind my taking a picture of his stronghold, so I set up my camera, and my friend the army stood bolt upright at one side. I should much have liked to have sent the little man a copy of it, for he was very attentive, and showed me the barracks of the state, a little four-roomed cottage covered with creepers. But, unfortunately, I find I did not turn my roller in taking the picture, so that when I come to develop I shall find a double image on the plate.

The prince himself, whom I had also the honour of meeting—you can't avoid him very well, for his territory is so small you are sure to see him whenever he is out-of-

doors—was very different to his smiling little soldier. He is tall, severe, and wears a fierce moustache. But then he has reason to be proud, for I hear that his income of florins, when translated into pounds sterling, amounts to nearly twelve thousand a year, so that he must be quite as well off as some of our lesser nobility or well-to-do city magnates.

Schwarzburg, notwithstanding its limited dimensions, is, nevertheless, a principedom to be proud of, for it is one of the most charming spots in Thuringia. The little village of Schwarzburg nestles cozily at the foot of the burg, or palace, which stands upon a leafy pedestal closing up the end of the valley. The scenery is like a bit of the Tyrol, and here and there is a stretch of green pasture land so smooth and even that it might be a soft carpet, trees that fringe the meadow on every side adding to the charm. The best view of the burg and its vassal village below is secured from a height called the 'Treppstein', where a summer-house has been built, with open windows so contrived as to appear like the framework of a picture.

Three ragged boys, my companion, and myself find ourselves up here; they have been blackberrying, and offer their wares to us in three little saucers. Blackberries are not, however, very rife in this part of the world, apparently, for twopence a piece is the price put upon the saucers. The boys go to school, they tell us, from six in the morning till half-past nine, and are then pretty well free to do anything they like. They address us as "highnesses," which causes my friend to ask them whether they have many princes like ourselves visiting Schwarzburg. In the end we buy their blackberries, but only on one condition: that they will sit down and behave themselves, and eat the berries as we look on, a condition they consent to amid a good deal of laughing and giggling.

We meet other visitors up here, and when I take my photograph, two young ladies are in the foreground as quiet as mice. I pack up my apparatus and walk off, but meeting the party some time afterwards they summon courage to speak on the subject of the photograph, of which they are naturally anxious to have a copy. But their spokesman falters before he has preferred the request, for he looks about for some signs of apparatus and camera, and seeing none, concludes he has made a mistake.

"I beg your pardon; I thought it was you who had been photographing."

"Yes," I replied.

"But I fear I have made a mistake."

"No; here is my apparatus, you see," and I pointed to my little leather case. "My pictures are only taken as reminiscences of my tour, or I should have been happy to have told you where to purchase them."

I hardly think my friends quite understood taking photographs for pleasure, for amateurs are not so frequently met with abroad as in England, where we have to thank them for much that has been done in the way of progress, and especially in connection with dry plates.

Across Kouigsee to Ilmenau is but a moderate day's walk, and I may give a hint here which some of my readers may like to have. There is nothing so refreshing as a cup of tea on a long walk, and I will mention how I obtained this beverage on the road-side with little trouble. There is to be purchased now-a-days a little flat kettle holding, perhaps, a pint, which weighs but a few ounces. A flat gauze spirit-lamp, containing sponge, so that it does not spill the liquid, is sold for ninepence, and this lamp has a stand attached whereon the kettle is poised. A four-ounce tin vial of spirit completes the outfit, which takes up but a small space in a tourist's sling bag. Inside the kettle are stored some tea and sugar, and with these appliances at hand a cup of tea can be made almost anywhere in ten minutes. The kettle is filled at a brook, and the lamp lighted down by the water where there is shelter from the wind; in five minutes the water boils, and in

goes the tea and out goes the lamp. Two tin cups which fit into one another are produced, and here we are drinking a cup of good English tea in the wilds of the Thuringian forest. And how nice the fragrant liquid is to a tired pedestrian I need not here set down.

Ilmenau is a forest town, well known as having been a favourite resort of Goethe, the great German poet. On the Kickelhahn hill, overlooking the little town, is a tower that offers a fine prospect over the country; and here, too, is the little house, restored since Goethe lived here, where he scribbled on the door-post with a pencil his famous ode to night:—

"Über allen Gipfeln
Ist Ruh',
In allen Wipfeln
Spürest du
Kaum einen Hauch.
Die Vögel schlafen im Walde;
Warte nur, balde
Ruhest du auch."

I take a picture of the Goethe cottage, standing on a shoulder of the Kickelhahn, and overlooking an expanse of foliage. From the Kickelhahn you can see right over to the Brocken of the Harz mountains, and secure a panorama of all Thuringia. Here there is a ruin on some lofty hill top, here the glistening towers or steeples of some little town or village. There is a story or legend connected with most of these old burghs, and a book, I hear, has recently been published of Thuringian legends which makes very pleasant reading. One of the best known of these is the story connected with the ruins of Kyffhaeusser, where the Emperor Frederick, old Barbarossa, called so from his long, tawny beard, is said to be still living down in one of the vaults of the ruined castle. They say that he sits upon a bench before a marble table, supporting his head upon his hand, dozing the time away, and every now and then he nods his head and rubs his eyes, as if about to wake up. His shaggy beard has grown right through the table, and now reaches to his feet. His courtiers stand silently around, and motionless, ready for the hour of awaking, and for the time when their old Emperor shall go back once more to rule the Fatherland. But this hour can only come, we are told, when the ravens that hover over the ruins fly away; or when Barbarossa's long beard shall have curled itself thrice round the table at which the old king sits.

RETOUCHING.

BY JAMES MARTIN.

SOME time ago, I urged some serious cautions on photographers, as to the excessive use of retouching: will you allow me to add a few remarks to what I then said, lest any of your readers might think that my strictures upon the practice of unlimited retouching then made were without due consideration. I will state the facts on which they are founded. A photographic portraitist works in a studio built expressly for his use, in which, if properly planned, he can command sufficient light from whatever direction may best suit his purposes. He has backgrounds, screens, and accessories, so that he is able to produce whatever effect he pleases. The pose of the sitter is also, or should be, entirely under his command. Therefore, if his skill be equal to the situation, he will be able to give the most agreeable representation possible of the subject. Further than this legitimate portraiture does not go. Any attempt made at idealism will result in loss of resemblance. The word ideal speaks for itself, as it signifies something which only exists in the imagination of the inventor, and is not the likeness of anything in existence. Should the idealised form be any way contrary to the laws of nature, it must necessarily represent a monster. Portraits are not treasured for the beauty or the fashionable attire of the originals, but they are intended to serve as lasting memorials of those

who are dear by the ties of kindred or affection, and from whom the changes of life or death have separated. A portrait album is not a thing to be exposed to the gaze of strangers, except it be filled with the representations of public characters; and here truth is *asine qui non*, as we are apt to look upon them with a philosophic eye, seeking to trace in their features some distinctive marks of the great qualities which we know them to possess. The expression of character is the very soul of portraiture, and any attempt at generalization destroys its chief attraction. With the landscape photographer, individuality is not paramount, therefore some poetical license may be allowed. In our variable climate, nature seldom shows herself in holiday guise, therefore it is perfectly legitimate—in fact, it is often necessary—for the photographer to be sufficiently an artist to be able to improve upon what he sees, always, of course, keeping the characteristics of the scene. Suppose, for instance, a view taken in dull weather, the introduction of a light cloud will give relief to the distant mountains on the horizon. A few touches of light will prevent the foliage of the trees appearing as huge silhouettes cut out of black paper. A diagonal graduated light thrown across a grass plot will prevent its looking like a dark wall. The representation of a few ripples or reflections will serve to distinguish a stream of running water from a pool of mud. The introduction of appropriate figures will enliven and complete the effect.

I have been only able to touch upon a few of the most prominent points suggestive of the direction in which the artist should work, neither am I able, in this article, to give any instructions concerning the method of working; but thus much I may say, that no double printing is necessary; on the contrary it will prove best to take some trouble to make the negative as perfect as possible, rather than have to resort to tedious, uncertain, and troublesome dodges to obtain each separate proof. I should be happy to offer a few practical suggestions for the guidance of beginners should you think it would benefit them.

Correspondence.

PHOTOGRAPHIC EXHIBITION.

SIR,—Will you allow me to call the attention of your readers to the fact that the last day for receiving pictures for the Photographic Exhibition is Tuesday, October 2nd. Intending exhibitors are particularly requested to comply with the published regulations, as any breach of them may lead to the non-acceptance of their pictures.—Faithfully yours,
H. BADEN PRITCHARD, Hon. Sec.

5, Pall Mall East, September 24th.

COLOURED LIGHT FOR WEAK EYES.

SIR,—Blue glass has long been used as the best medium for softening the light for weak eyes. Recent correspondents, however, favour yellow glass for this purpose. The objection against blue glass seems to be that it does not admit enough of light, and against yellow glass that it makes a glare. Both these objections might be obviated by a compromise, viz., green. This is the colour of the foliage and herbage which surround us on all sides; and it is a known fact that it is a rest for the eyes to look on a green lawn or on foliage from a brighter light, such as is reflected from the white paper of a book. For these reasons I think that green glass is preferable either to blue or to yellow.—I am, sir, your obedient servant,

A GREEN LIGHT.

GERMAN PHOTOGRAPHIC LITERATURE.

SIR,—On perusing the News of the 21st inst., I read, under the heading "Photographic Literature," that the "*Deutsche Photographen Zeitung*" will constitute the only

weekly photographic journal in Germany, unless the *Wochenblatt* is still in existence. I conclude from these words that you think our *Photographische Wochenblatt* has ceased to live, and therefore beg to inform you that the establishment of the *Deutsche Photographen Zeitung* will by no means affect our journal, as its existence is positively secured by a considerable capital, first rate contributors, and a great number both of subscribers and advertisers.

Trusting you will publish these few lines in your valuable journal, I am, sir, yours very truly,
EMER DUNN.

[We have much pleasure in receiving the assurance of the intended longevity of our energetic and excellent contemporary.—Ed.]

TRANSPARENCIES.

SIR,—I send a new process for making transparencies. The process is as follows.

Soak some gelatine in sufficient water for five hours, and then dissolve by heat. Pour double the quantity of methylated alcohol into it; let it stand for a few minutes until the gelatine falls to the bottom of the bottle, and pour off the water and alcohol. When perfectly drained, add the same quantity of water as first employed; let it soak a little while, and then dissolve the whole by heat; add some drops of glycerine. For use—

Solution of the gelatine	...	1 ounce
Bichromate	...	3 ounces or less
Water colour, or Indian ink	...	quant. suff.

Take a varnished negative, coat it with waxing solution; when dry pour a little of the bichromated gelatine on it, and spread with glass rod; let it dry, as it will in a few minutes. Place a piece of black velvet on it. After exposure, wash it with warm water as usual.

CARELESS OPERATOR.

PAINTING PORTRAITS IN OIL.

DEAR SIR,—With regard to the subject of painting portraits in oil, I would observe that I have noticed a practice which I consider amounts to a deception unworthy of art, viz., the use of paper enlargements pasted upon calico or canvas as a basis. From the nature of these materials they cannot be expected to resist injury, damp, and the effects of time, and, therefore, the purchaser's intention is frustrated, and the expense to which he has gone has brought little or no return. The various gradations of shade in the enlargement being obliterated by the opaque colour used in painting the picture, they become useless; therefore it would be much better to make an outline upon a properly prepared canvas, either by a photograph from the photographic enlargement, or, when of the same sizes, by superposition, which is easily done, without spoiling the enlargement, by rubbing over a sheet of thin paper of sufficient size with either common blacklead, lampblack, red chalk, or any powder colour. With the exception of blacklead, a small quantity of soap or grease should be mixed with them, which will make them adhere better to the paper, and not be likely to smear. Place a sheet of this paper (coloured side downwards) on the prepared canvas on which the portrait is to be painted; over this place the photographic enlargement face upwards; fasten the whole together firmly by drawing pins, or by any other means which will allow the two papers to be lifted in parts without displacing them, so that the operator may observe, from time to time, how the work progresses. Everything being nicely arranged, proceed with a moderate pressure to trace on the face of the enlargement its outlines, using a blunt style. On removing the papers, if carefully executed, a correct outline will be found on the canvas, and the photographic enlargement will prove of further service as a copy.

While on this subject I may notice a deception practised by unprincipled picture-dealers of foisting upon unwary purchasers oleographs got up to represent original

paintings, principally by the old masters. There is no doubt that this style of print is a vast improvement in pictorial art, affording, as it does, almost facsimiles of high class pictures, and when sold for what they really are, and at a moderate price, offers a boon to the public. But cases have come under my notice of a very serious imposition; it is not always that a magnifying glass will detect them, as the prints may have been worked upon for the express purpose of deception. The best way is to remove the picture from its frame, when it will appear as if it had been re-lined; remove a little of the paper generally pasted round the margin; then remove a bit of the picture itself from the canvas at a corner; the material on which the picture is painted (should it prove to be paper) will at once disclose the deception.—I am, dear sir, yours truly, JAMES MARTIN.

Proceedings of Societies.

EDINBURGH PHOTOGRAPHIC SOCIETY.

AN out-door meeting of this Society was held on Thursday, the 20th instant, the scene of operations being Largo, one of the numerous quaint fishing villages on the East coast of Fife famous for its connection with the popular song "The Boatie Rows," as well as being the birthplace of the celebrated author of the ever fresh romance of "Robinson Crusoe." It stands at the head of the bay, and affords, both in the harbour with its fishing-boats and in its straggling and often picturesque houses, some capital work for the camera, while within easy distances are several ruined towers, or castles, and an interesting Roman monument well worthy of being visited.

In consequence, not so much of its distance from Edinburgh, as of the out-of-the-way corner in which it lies, the necessity for crossing the Firth of Forth, and the limited train service, an early start was necessary, and so the party left the Waverley Station at 6:25, and reached Largo at 8:30, quite ready for a good breakfast, although, as it turned out, it was not so ready for them. As the worthy treasurer was the only member who had not brought his camera, he was despatched to commissariat duties, while the rest went on exploring expeditions, and, as the morning was fine, the light all that could be desired, and hardly a trace of wind, all were sanguine of a successful day.

"But ah! how little mortals know
When chance may prove their friend or foe."

Largo contains two inns, the "Railway," and the "Crusoe," and the commissary, believing that it is true of hotels as of men, that a good deal can be learned from external appearances, resolved to reconnoitre a little, before deciding as to which he should patronize. There was, however, not much to choose between them, except, perhaps, the windows of the one were cleaner than those of the other, and having a leaning to the ancient rather than the modern, he applied to the "Crusoe," but applied in vain. Like its prototype, it would have gladly taken in one, but on no consideration would it undertake to breakfast the party. Well, of course, there was no help but to try the "Railway"—surely he would succeed there! Its very name implied progress, and hinted at preparation for travellers; but, alas! his application there seemed at first doomed to share the fate of that made to the "Crusoe." The good wife of the "Railway" thought she could manage one, or perhaps two, but there really was nothing in the house to breakfast as many as he wanted to cater for. Fish, the commissary suggested—surely Largo Bay had still plenty of fish! But no; the fishermen had either not cast their nets, or, if they had, they had not caught even the classic "nine," as there were only three available: and what could they be amongst so many? However, after considerable persuasion, the landlady agreed to do the best she could, stipulating that they must be satisfied with the three fishes and as many eggs as they could eat; and as "hunger is good kitchen," they enjoyed the breakfast thoroughly. By the time it was finished the clouds had gathered in, obscuring the sun and casting a gloom over the hitherto cheerful prospects for the day, the sky having assumed that dull leaden appearance which usually betokens a continuation of the same. They proceeded to the harbour, however, and several plates were exposed there by the younger members; but the older and more experienced—and, perhaps, too, less enthusiastic—decided to give it up as a bad job, and

return to Edinburgh by the first train, considering the flat, uninteresting pictures that could only be got in such a light not worth the trouble of taking. But by the time Burntisland was reached an unexpected change had taken place, and the sun had again put in an appearance. Here they remained and exposed a number of plates, some on the shipping in the docks, and some on the not unpicturesque street.

By five o'clock the plates were exhausted, and the party adjourned for refreshments, after which Mr. Pringle took the chair, and some routine business was transacted, and Mr. Lawson admitted an ordinary member.

The plates included the ordinary collodio-bromide and gelatine as modified by Mr. Gray, and the exposures varied from ten seconds to thirty minutes, the former proving quite long enough for the gelatine.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE first meeting after the summer recess was held at the Memorial Hall, on Thursday evening, the 18th inst., the President, Mr. ALFRED BROTHWELL, F.R.A.S., in the chair.

In the absence of the books through misadventure, the confirmation of the minutes was postponed until the next meeting.

Mr. COORS exhibited a number of fine collodio-albumen negatives taken during his summer trip to Connemara.

Mr. M. NORON showed and described a new method of arranging the camera front [in our next].

Mr. LUND exhibited a collodio-albumen plate, prepared by Mr. Pollitt in 1869. This plate was exposed by Mr. Lund about September last year, and developed on the 12th instant. The result was a good, clean negative.

As is usual, the first meeting of the season was poorly attended, and the members present busied themselves with the Society's portfolio.

After a vote of thanks had been accorded to Messrs. Coats, Norton, and Lund, the meeting was adjourned.

Talk in the Studio.

CATALOGUE.—We have received a copy of the catalogue of chemical appliances manufactured and sold by G. Mason and Co., of Glasgow. For all engaged in chemical operations this catalogue will be invaluable. It is singularly complete, admirably arranged, and well illustrated. It is not needed by the photographer for his ordinary working appliances; but to all engaged in chemical and experimental work we strongly recommend an examination of this catalogue.

SHERIFFS FOR LONDON.—The inauguration of Mr. Alderman Nottage and Mr. Alderman Staples as sheriffs for London and Middlesex will take place to-day at the Guildhall. The procession will leave the Albion at half-past twelve, and pass through Aldersgate Street, Barbican, Redcross Street, Finsbury Street, Aldermanbury, Gresham Street, into Guildhall Yard, returning to the Albion by way of King Street, Chesapeake, and Aldersgate Street.

MR. BRIGHT ON PHOTOGRAPHY.—In a recent speech on Progress in Science and Art, Mr. Bright said:—"If you come to the science or the art, whichever you may call it, of photography, that is entirely new. Many of us who have lived a good while in the world have no portraits of our parents—our parents passed away to the future life before this great invention was made; but now in every family parents can have portraits of their absent children; children can have portraits of their absent parents; we can have portraits, as no doubt most of us now have, of those who have loved us, and whose features we shall see no more here; and all this is brought into every home at the smallest charge, not to the rich alone, but to the poor everywhere, for science is not a respecter of persons, but is good to everybody to whom it comes near, and with whom it deals."

WRACK OF THE "FORSTER."—Two photographic pictures in a cigar-box have been picked up off Whitesea Coastguard Station. The pictures were on glass, and in an old style of art. One of these consisted of the likenesses of three young men, who appear to resemble colonists from the style of their dress and other surroundings. The other picture was the portrait of a young woman.

A NATIONAL COLLECTION OF PHOTOGRAPHS.—"One of the Many" writes to us (*Daily News*):—"May I ask the help of your valuable paper in proposing that the National Gallery authorities be persuaded to make and exhibit for public benefit a national collection of photographs that should show by means of permanent fair-sized photographs, taken from the objects themselves—as complete a collection as possible of the time-honoured treasures of painting, sculpture, and architecture—the relics of the best times of art that those who travel go abroad to see. Thus, the collection should comprehend photographs of each of the famous buildings and valued ruins; those of a kind hung together, and grouped according to their style, with photographs again of rich details enlarged. It should show the famous pictures, each artist's works being hung together, and grouped by their subjects. The antique statues and bas-reliefs; those of the same personages together and grouped by their attitudes. And Michael Angelo's statuary. Lastly, the whole number of photographs should be repeated on a small scale, grouping them according to the towns to which each object belongs. Such a school as this collection would be ought to improve gradually the art of the country, when architects and they who employ them—painters and sculptors, and they who judge their work—have the power of seeing and growing familiar with the best samples of the sublime and beautiful in art that the world boasts. Plenty of the objects have already been photographed, and only need collecting; numbers would have to be taken expressly, but the expense would be small in comparison with the advantage, which would be very great. The collection might well find a place on the walls of the ground floor under the National Gallery."

To Correspondents.

L. D. L.—Is the patent lens in question the back lens can be separated by unscrewing, so as to produce diffusion of focus. Where you do not require that kind of definition you can keep it screwed tight up. The maker of any apparatus will, as a rule, furnish you with the fullest and most satisfactory information as to its objects and mode of using.

CARELESS OPERATOR.—We know nothing of the matt paper to which you refer, and the portion of advertisement you enclose affords us no clue, as it mentions no advertiser's name. Write to the advertiser (whose address you have doubtless retained), and ask him for information. 2. Unless you are familiar with, or master of, some dry plate process, you had better use the wet process for enlargements.

JOHN SALT.—All the tools mentioned in the article to which you refer can doubtless be obtained at a hardware shop, or of a dealer in tools. Many workmen make a mitring block themselves; it is not a difficult task. We cannot give you any information about the prices of tools.

NEGATIVE.—There are many manuals of photography for beginners. There is, however, none better than Captain Abney's *Instruction Book*, sold by our Publishers.

T. R. R. sends us a negative packed between two pieces of mill-board, for transmission through the post, and remarks that he packs it thus carefully to try the experiment, and wishes to know in how many pieces it arrives. We hope the experiment is satisfactory to him, for it came in more fragments than we have time to count, and each of too small a size to afford us the slightest clue to the character of the negative, upon the defects of which we were requested to advise. The primary intention of sending the negative is therefore sacrificed to an experiment which should not require making. It is quite impossible that a glass negative can pass safely through the post, subject to the stamping operation and other risks of transit, without properly packing in a box. If, by rare chance, this negative had come without fracture, it could have been no proof that another would do the same. We must warn our readers that on receiving a post packet containing broken glass we generally throw it away at once, as opening it on a writing desk covers everything with minute fragments, dust, and specula or broken glass, at once dangerous and uncomfortable. As you do not describe the defects of the negative, we have no data upon which to offer advice. 2. The spots of the sensitive paper are clearly due to dust of some kind; iron rust would produce such an effect, as almost any reducing agent would. It is not hypo, certainly.

M. D.—We do not know of any systematic application of photography to the delineation of morbid anatomy. It has frequently been employed for preserving records of special cases, but not systematically applied, so far as we know. The late Dr. H. G. Wright took great interest in the subject, and made a collection of all the photographs of medical subjects he could obtain. Dr. Diamond applied photography to the portraits of the insane, and made a valuable and interesting collection.

F. A. G.—Fargier did expose the sensitive film of gelatine and pigment on one side and develop on the other, but in an awkward and inconvenient fashion. He coated a plate of glass with the brominated gelatine, and exposed under a negative whilst on the glass; then coated the film with plain collodion, and plunged the plate in warm water to develop. The collodion film with the image attached eventually floated off the plate, and was removed from the water and mounted. It is clear that this method was only available for very small pictures. The Abbe Laborde and M. Poitevin in France, and Mr. Blair in this country, had previously pointed out the principle of exposing on one side and developing on the other as the true solution of obtaining half-tones in carbon, but had not devised efficient means of effecting this object. It was Mr. Swan who originated an efficient means of doing this.

CORRECTION.—We have received a letter from the editor of a contemporary stating that the article on glass which appeared in our last, accredited to the *Scientific American*, originally appeared in the *British Journal*, and should have been accredited to that journal. We can simply explain that the cutting was sent to us by a friend who had clipped it from another journal where it was accredited to the *Scientific American*, and we reproduced it as it was printed. We give our contemporary's claim as he makes it without question or doubt, and we consider we paid him a high compliment in considering that the article was good enough to reproduce in our pages.

J. W. G.—For a beginner having had no tuition and little experience your work is promising. The printing and toning are good. The most prevalent fault is a lack of definition, either from imperfect focussing, or movement in the sitter. You will improve by observation and care in the pose, arrangement, and general artistic qualities of the work.

Several Correspondents in our next.

METEOROLOGICAL REPORT FOR AUGUST.

BY WILLIAM HENRY WATSON, F.R.S., F.M.S.

Observations taken at Brayton, near Whitehaven, 36 feet above sea-level.

Date.	BAROMETRIC PRESSURE.			TEMPERATURE IN THE SHADE.			REMARKS.
	Morning.	Noon.	Night.	Morning.	Noon.	Night.	
1	29.75	29.78	29.75	59°	61°	55°	Fair, generally cloudy.
2	29.79	29.80	29.81	59	60	56	Fair, generally cloudy.
3	29.79	29.80	29.82	58.5	—	53	Fair, generally cloudy.
4	29.84	28.85	29.90	60	62	58	Fair, generally cloudy.
5	29.90	29.9	29.83	61	72	64.5	Fair and sunny.
6	29.74	29.70	29.61	62	72	60.5	Rain p.m.
7	29.40	—	28.25	68.5	69	61	Rain a.m. and p.m. [ning afternoon]
8	29.19	29.14	29.20	63	70	62.5	Rain a.m. and p.m. Thunder & light-
9	29.32	—	29.30	62	63	60.5	A little rain this morning and evening
10	29.46	29.53	29.75	60	64	57.5	Rain showers about five p.m.
11	29.81	29.82	29.82	62	62	55	Fair, generally cloudy.
12	29.95	—	29.99	63	66.5	59	Fair and sunny.
13	29.8	29.80	29.67	64	74	62	Fair and sunny.
14	29.75	29.75	29.75	68	77	62.5	Fair and sunny.
15	29.72	29.73	29.78	68	68	60	A little rain this afternoon.
16	29.70	29.64	29.70	68	70	63.5	Rain this evening. Lightning at night
17	29.75	29.80	29.8	66.5	66	64	Fair, generally sunny.
18	29.66	29.76	29.73	63	66.5	62	Rain a.m. and p.m.
19	29.58	29.54	29.50	62	67	61	Rain a.m. and at night
20	29.48	29.43	29.39	63	67	64	Rain a.m. and p.m.
21	—	—	29.43	60	—	58.5	Rain a.m. and a little p.m.
22	29.43	29.48	29.48	54	56	60	Rain a.m. and p.m.
23	29.79	29.65	29.61	63.5	60	57.5	Showers about noon.
24	—	29.94	29.94	58	—	53	Fair, generally sunny. Thunder and lightning early this morning
25	29.87	29.89	29.43	61	63	59	Rain this evening
26	29.81	29.60	29.71	57.5	60	53	Fair, generally sunny
27	29.55	29.61	29.60	58	64	62	Rain p.m.
28	29.58	29.50	29.58	62.5	68	57.5	Rain a.m. Windy
29	29.61	29.68	29.57	63	61	54	Fair and sunny.
30	29.40	29.48	29.68	54	61	61	Rain a.m. and p.m. Lightning at night
31	29.50	29.67	29.60	53	58	52.5	Showers a.m. and p.m.

Summary.				Mornings. Noons. Night.		
Highest temperature observed	68.5°	77°	64.5°
Lowest ditto	53	56	47.5
Mean ditto	61	63.5	58.5

Mean of all observations 61° 5
 Number of fair days 13
 Number of days on which rain fell 13
 Number of fair days sunny 7
 Number of fair days gloomy 6

NOTE.—I see nothing particularly worthy of comment in the observations of last month (August), but it may perhaps be interesting here to note the exceptional height of the barometer yesterday and to-day, as follows—

	Morning	Noon	Night
September 30	29.13	29.20	29.16
" 1	29.20	29.28	29.23
" 2	29.23	—	—

After the particularly wet weather during the whole of this year, may we hope this to be the commencement of a fine autumn!

September 18th.

The Photographic News, October 5, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO.

HOW SCIENTIFIC EDUCATION IS CONDUCTED IN AMERICA—

DR. STEIN'S LAST SCIENTIFIC APPLICATION OF PHOTOGRAPHY—SOLUTION OF SILK ONCE MORE—A SIMPLE TEST FOR THE HALOID SALTS OF SILVER.

How Scientific Education is Conducted in America.—Our American cousins have conceived a bold idea for educational purposes; it is no less than a scientific and educational expedition round the world. And if this, the first experiment, is successful, we may hope to see such a tour form one of the ordinary items of education with New England youths. America is used to "big things," and our cousins think nothing of an excursion which takes the best part of a year to execute. As to journeying across the Continent to Frisco and back, why, that is merely a matter of days; and if a train on its way over the prairie gets pillaged by a party of marauders, as was the case only the other day at Big Springs station, why that only adds to the excitement of the journey and to the experience and education of the traveller. In the end, too, we suppose, accident and loss of life from railway travelling is less in the United States and Canada than with us, although, it is true, in this, as in everything else, "big things" are not unfrequently met with. The scientific and educational expedition to which we refer seems to have been projected by a Mr. Woodruff, of Indiana, and the extent of the scheme may be imagined by the circumstance that accommodation is arranged for four hundred students. A steamer, the *Ontario*, has been fitted up with berths to accommodate this number, and large cabins for study are to be improvised. Science, both natural and experimental, is to form the main instruction on board, and six professors are part of the staff. A photographer will also accompany the expedition professionally, who will be provided with every requisite for carrying on his duties efficiently; but many of the students who come on board will be, doubtless, amateur photographers themselves, or develop into such before they get far on their voyage. Besides the six professors and photographer, the staff is to consist of a chaplain, a chief engineer, two surgeons, and five naval officers. The experience of the last will be very necessary, for the *Ontario* is to visit many out-of-the-way ports and islands of the globe, the students making excursions inland at most points of interest. Here studies will be made of the animal and vegetable kingdom, and geological and chemical instruction imparted, while, as a matter of course, the camera is to be busily employed in securing pictures of objects of scientific and general interest. A more instructive voyage can scarcely be conceived, but it is one in which young men, rather than youths, should participate—those, namely, who can realise to the utmost the advantages they enjoy. It is, probably, the voyage of the *Challenger* which suggested to Mr. Woodruff this grand scheme, for not less than two years will be passed in this expedition round the world—ample time, we should think, to visit all quarters of the globe. The expedition starts from New York, we are informed, on the 25th of this month, so that those in this country who are contemplating the voyage must lose no time in making up their minds. A charge of five hundred dollars represents the price of a ticket, which gives students their cabin and food, and includes all fees to professors, &c.; a large sum, it is true, but scarcely an exorbitant one, taking all circumstances into consideration.

Dr. Stein's Last Scientific Application of Photography.—Dr. Stein, of Frankfurt, whose name is familiar to our readers as one who has done much to apply photography to scientific purposes, has now succeeded in constructing an apparatus for recording minimum periods, or, in other words, acting like a time-piece to register lapses of times of the briefest character. Dr. Stein has already constructed an

instrument, and another, not less ingenious, for photographing sound, or, rather, the vibrations upon which sounds depend. The minute waves written down upon the sensitive plate are, in both these cases, so fine and delicate as to bear magnifying to a high degree, and hence we are made acquainted with phenomena which take place in the fractional part of a second. In the present case, apparently, Dr. Stein has no difficulty in registering thousandths of a second, the time that the light is shining upon his plate being shown by an index that can be read by anyone. Electricity, as may be guessed, is employed for opening and shutting the lens, and this movement, we are told, takes place within thirty-five-thousandths of a second. His instrument is to be employed for measuring the speed of various bodies, and for delicate mathematical work. A similar apparatus, only not photographic, has been in use by physicians for some time, to determine the velocity of nerve sensations, when thousandths parts of a second also form the unit; and it is, doubtless, in connection with such an apparatus that Dr. Stein has employed photography. Again, in estimating the time which elapsed in a cannon ball rushing through the bore of a gun, an arrangement of the same kind has also been in use. In this case the readings are made with the eye at the close of the experiment, but Dr. Stein's apparatus would, no doubt, record the result photographically. The last application is but another indication of the assistance which photography lends to scientific research.

Solution of Silk once more.—Substitutes for collodion are not easily found, and, indeed, the only two bodies that have been employed with any success as a vehicle for sensitive salts are our old friends albumen and gelatine. At one time, however, another body was brought forward, and, for a while, bade fair to be applicable by photographers: we mean solution of silk. Persoz employed chloride of zinc for dissolving silk, and after him came Spiller, who found that the material dissolved readily in hydrochloric acid. Another chemist (Schlossberger) employed nickel-ammonium oxide to dissolve the silk, and now a fourth method is suggested by Lowe, who uses an alkaline glycerine-copper solution for the purpose. We may, therefore, expect that renewed efforts will be made to make some use of silk in solution as a substitute for collodion. Both Persoz and Spiller endeavoured to secure results with sensitive salts, but their experiments do not appear to have been attended with much success. So far as our experience of silk solution goes, the film deposited on drying is deliquescent, and hence it is ill-adapted for printing purposes. But we cannot help thinking that research in this direction would be well worth taking up by chemists.

A Simple Test for the Haloid Salts of Silver.—A German chemist, Herr V. Goldschmidt, cites a very simple method of examining the chloride, bromide, and iodide of silver with the aid of the blowpipe. These three compounds are in many respects so similar that the trustworthy test furnished by Herr Goldschmidt will be gratefully received, and especially by photographic chemists. The ordinary test conducted by fusing the chloride and bromide with bisulphate of potassium does not give accurate results, whereas that proposed by the author is at once to be relied upon, and very simple in its nature. He scoops a cavity in a flat surface of charcoal, and places therein the silver compound to be examined with some powdered sulphide of bismuth. This sulphide of bismuth, by the way, is easily prepared by fusing bismuth with flowers of sulphur. A blow-pipe flame is then applied. If a bright red incrustation is the result of this heating together of the silver compound and sulphide of bismuth, the former is proved to have been iodide of silver; if a deep yellow incrustation results, the silver compound was bromide; if the incrustation is white, it is a proof that chloride of silver was present. These incrustations are said to be very volatile, and are formed at some distance from the cavity of the charcoal. Photographers have, therefore, a ready means

of ascertaining the nature of a silver compound, and distinguishing one from the other, the only apparatus necessary for the purpose being an ordinary blow-pipe and a bit of charcoal.

EXPERIENCES OF LICHTDRUCK PRINTING.

BY JOSEPH LEMLING.*

THE glass plates necessary to Lichtdruck work are now to be purchased in commerce, so that the photographer or Lichtdrucker is no longer required to follow the laborious operations involved in polishing one plate against another to render them smooth and level. Plates which have already been employed in Lichtdruck I allow to remain four-and-twenty hours in an alkaline lye of wood-ash or soda, and then scrape with a knife until the softened film has been removed; a final rubbing of the surface with powdered pumice removes from the pores of the glass the last traces of the preparation that has been applied.

For Lichtdruck purposes may be employed also, with success and simplicity, copper plates (not brass) specially prepared for such use. The plates are very thin, and are fastened to an even basis of some thickness; the sensitive film in this case consists of gelatine, water, and chrome salts, without any other addition. The film applied to the matt-ground copper plate attaches itself very firmly, and the printing is very convenient. The progress of the printing in the frame may be watched by the aid of strips of silver or bichromate paper. As formula for the sensitive film, I recommend:—

Chrome salts	1 part
Gelatine	5 to 7 parts
Water...	50 to 70 „

Of the drying of the sensitive film—the most important part of the work, because success depends so much on it—I will speak at a later period, as also on the subject of the influence of more or less chrome salts.

The printing-film requires a preliminary film in order to hold it fast to the glass plate. In this case a thin film consisting of white of egg, gelatine, and water, or only of white of egg and water, and so much chrome salts that it does not crystallize out on drying between 20° and 25° Reaumur, may be employed. A mixture to be recommended is:—

Water	480 parts
Gelatine	22 „
White of egg	240 „
Chrome salts	12 „

This mixture has the advantage of drying in an ordinary warm room, and there is not sufficient bichromate to crystallize out. Plates coated in this manner may be preserved, supposing they are kept dry and screened from the light, for a week or a fortnight. The film or matt surface of the glass plate is placed upon a black cloth, and then exposed to diffused light from the back. With a little practice it is easy to judge the time of exposure by the tint of the film.

The under-film must possess two properties, it should be remembered: firstly, it should be capable of adhering firmly to the glass plate; and secondly, it should hold fast to the second film. The first property is wanting when the exposure has been too short, the second if the exposure has been too long. Another film which I can strongly recommend as a preliminary coating is that resulting from:

Water	45 parts
White of egg	35 „
Saturated bichromated solution	15 „

The drying of this film must not, however, take place under a temperature of from 20° to 25° Reaumur.

* Photographische Correspondenz.

Diluted soluble silicate will also give a very good preliminary coating without any white of egg or bichromate at all, but in this case a moist atmosphere must be studiously avoided, so that the film may not suffer.

It is in Lichtdruck as in all other branches of photography: one operator works with this formula, another with that, and prefers one to the other according as he gets the best result and grows used to it. Some people tell us such and such an addition to the gelatine is necessary, others again that it is positively injurious. The most useful addition—although it may not be necessary for all sorts of gelatine—is white of egg, and this only in small quantities.

The mixture employed for the upper film may be the simple one to which I have referred, or another of a more complicated character. The production of the film and the drying of the same require practice and experience. The gelatine, though it may always be drawn from the same sources, varies very much in character. For this reason it is obvious that a process in which merely water, gelatine, and bichromate are employed, cannot be always governed by the same principles, and modifications must from time to time be adopted, according to the properties of the mixture. I may mention, however, the result of some of my experiences. Very concentrated gelatine solutions yield a rough printing grain. For some gelatin films—as, for instance, those which set easily at 15° R.—the proportion of the material to be employed should be one part gelatine to eight or ten parts of water; other gelatines will only yield a fine printing grain with twelve or sixteen parts of water.

The same result is not to be obtained with other descriptions of gelatine, even with great care, unless white of egg is added. Even when a thin gelatine solution produces a thick film, which contains enough chrome salts, and dries at a high temperature, the salts become decomposed and the gelatine changes in such a fashion that the resulting grain is as coarse as that of a rough lithographic stone. Under such circumstances the production of fine prints is of course, simply impossible. Thin films, which dry too rapidly, betray, after washing, scarcely any relief at all whether much or little bichromate is contained therein. Such films are also unsuitable for collotype printing.

A high temperature for drying, as is frequently recommended, is highly detrimental. In such matters much depends, of course, upon the nature of the gelatine and the salts it contains, and also upon the temperature at which it was in the first instance produced. The chrome salt, according to its nature, whether it is ammonia or potash exercises also considerable influence. The more concentrated the chrome salt, the rougher will be the resulting film. Too little bichromate, on the other hand, will give rise to flat impressions.

The employment of too much white of egg, again, is fraught with disadvantages. I have had to do with gelatines which, if not mixed with other descriptions, were quite unable to produce Lichtdrucks in any way, for they never yielded pure prints. Certain sorts of gelatine, which are peculiarly suited for Lichtdruck purposes, and are recommended by makers, and command high prices, have in my experience, frequently turned out less favourable than that obtained from the ordinary druggist. There is gelatine to be had which only gives good and delicate impressions when the film is dried without any admixture of bichromate, the latter being applied afterwards in the form of a cold saturated solution, to which a little sugar has been added. This addition I have recommended for years past, the film being afterwards dried at a mild temperature. The mixture of bichromate and sugar should only be permitted to act upon the gelatine for a brief period—say thirty seconds. It is in this way that I prepare photo-lithographic paper: I take stout, fine paper, and having applied the mixture and exposed, put it for a short time in cold water; it is laid wet upon a glass plate, and

then inked up with a litho roller. In this way I get a much finer transfer than is usually the case.

As regards the ink to be employed in Lichtdruck, it must, firstly, not be crumbly; secondly, not too tough; thirdly, not so firm that it will not spread in fine layers; and, lastly, it must not be too soft or smeary. A colour which is too tough and firm, rubbed with a little linseed varnish or linseed oil, yields a very suitable ink.

In choosing colours of various tints, all those must be excluded which act as a mordant, or have a tanning effect upon the gelatine film; also all such colours which bleach or darken by light should be rigidly excluded. There are quite sufficient of fleeting photographs in the world, without our adding Lichtdrucks to the number.

The purpose of the Lichtdruck process is not only the production in a rapid and ready manner of photographs, but to obtain them of a permanent character; it is only by the execution of solid work that we can retain the confidence of the public.

In conclusion, I will here set down the answers to some questions which are frequently asked by those who are interested in the production of permanent photographs:—

1. Have carbon prints any real future, considered from a business point of view? My answer is: Certainly, in the case of a certain number of copies from one negative being required.

2. Is it a wise and paying speculation for a photographer or lithographer to introduce Lichtdruck or any similar branch of photography into his business? I reply: Without doubt, if he has means at his disposal, and has opportunity to learn.

3. In what direction is Lichtdruck to be employed in a profitable manner? I answer: In every direction and on every occasion that a large number of copies of any one cliché are required.

THE LATE W. H. FOX TALBOT.

(From the ATHENÆUM).

MR. WILLIAM HENRY FOX TALBOT, F.R.S., died at Lacock Abbey, on the 17th inst., at the advanced age of seventy-eight. Mr. Fox Talbot's name is intimately associated with the processes by which pictures are obtained by the influence of the sun's rays. Long before the announcement that Daguerre, in 1839, has discovered the process which bears his name, Mr. Talbot, in the quiet of his ancestral home, had been at work quietly following out the indications which Wedgwood had left behind him. No sooner had it been whispered that Daguerre could obtain pictures by solar influence, than Mr. Fox Talbot exhibited to his friends pictures which he had taken, and he published in the *Philosophical Magazine* an account of his "photogenic" process. Those, the first photographs on paper, were but imperfectly fixed, and they soon faded, or became greatly impaired in beauty. Sir John Herschel commenced his photographic researches, and to him belongs the merit of having introduced an agent (the hyposulphite of soda) by which those photogenic drawings could be rendered permanent. A letter describing Daguerre's researches will be found in the *Athenæum* for January 26th, 1839 (No. 587). Mr. Fox Talbot's paper read before the Royal Society was noticed in the *Athenæum* of the following week, and printed for the first time in the number for February the 9th of that year.

Mr. Fox Talbot zealously pursued his experiments, and he was within a comparatively short time rewarded by the discovery of a process (in 1840), the Calotype, which well deserved the name he gave it. This highly sensitive photographic process owed its sensibility to the discovery that a latent image, produced by the shortest possible exposure to the sun's rays, could be rendered visible by the action of gallic or pyrogallie acid.

The discovery of this process, which was sufficiently sensitive to secure delicate portraits, started many chemists and others on the path of photographic enquiry. The result of this was that the collodion process was discovered by Mr. Scott Archer, and this, at one step, removed photography, by its exquisite sensibility, and its extreme facility, from the closed circle of scientific inquiry, and placed it in the hands of the public. Mr. Fox Talbot had—as we think, most unfortunately, and very unwisely, patented his photographic process, and this led, after the development of the collodion process, to an action at law, for the purpose of determining if the development of a dormant image on paper—no

matter by what agent—could be secured to the patentee. The decision was against Mr. Fox Talbot's claim, and this led him to abandon a field of inquiry with which his name must be forever associated.

Mr. Fox Talbot's scientific researches were not confined to the chemical agency of the sun's rays; he was an earnest inquirer into electrical phenomena, and made numerous experiments to determine if it were possible to apply electricity, or magnetism, as a motive force. None of these led to any practical result, but many of the machines constructed showed great mechanical ingenuity, and exhibited considerable philosophical investigation, as well as many most striking experimental results.

In compliance with an invitation from Messrs. Sampson Low and Co., Mr. Talbot was latterly engaged in writing an account of his early researches and discoveries in photography, to form an appendix to the second English edition of Tissandier's "*History and Handbook of Photography*," to be published shortly. This account, which will be illustrated by two specimens of heliographic copper-plate prints, made by Mr. Talbot, will doubtless be much valued by all interested in the beautiful art towards the perfecting of which Mr. Talbot did so much, and with which his name will be ever connected.

[From the STANDARD.]

SOME eight-and-thirty years ago there used to be visible in the corner of an optician's shop window in Regent Street a pale and dingy vignette, on which, probably, few passers-by ever cared to bestow a glance, unless it were those inveterate *flâneurs* to whom the contents of shop windows, be they ever so humble, are a source of perennial delight. The little picture somewhat puzzled the inquisitive, since, with all their lengthened experience, they were fain to confess that they had never seen anything of the same kind before anywhere else. It was on a thin, yellowish paper, and its hue was a monochrome of an uncertain bistre; but whether the thing itself was a mezzotint engraving, or a lithograph, or an Indian ink drawing, none but the initiated—and the *flâneurs* were not then initiated—could tell. It represented only a few shelves full of variously bound books; but the marvel about it was that every particular volume, from bulky folios to ragged-backed paper pamphlets, was delineated with an accuracy of draughtsmanship and a microscopic fidelity in texture and detail which might have aroused the envy of a Gerard Douw or a Wilkie. No modern præ-Rafaelites ever produced such exquisite "finish" as was visible in the contents of those miniature shelves; and, abating the depressing sepia tint pervading the whole, the books looked alive—as much as objects of still life could look, indeed. What human hand had executed this curious performance? The artist came to be known afterwards well-nigh simultaneously in England and in France. His name was Sol, otherwise Phœbus, sometimes called Apollo, and thousands of years since a blind poet dubbed him the "Lord of the Silver Bow." He was, in short, the Sun, whose magic pencil had been pressed into the service of an ingenious mortal—a modest English gentleman named Fox Talbot, who died a few days since at the good old age of seven-seventy—and the shallow little vignette in the optician's window was one of the earliest known specimens of that which was subsequently called the Talbotype. It was the infant Hercules. It was photography in its cradle. The tiny thing has faded away, perchance, these many years past, or has been relegated to the limbo of waste paper; but if it be yet in existence it should be prized by its possessor as charily as though it were Stephenson's "Rocket," or Tycho Brahe's telescope.

When another Beckmann compiles a fresh "*History of Inventions*," he will be false to his trust if he fails to record that a more open-hearted, simple-minded, or self-denying philosopher than the late Mr. Fox Talbot has rarely existed. He never claimed to be the original inventor of heliography. He knew perfectly well that Wedgwood had made public the results of some partially successful experiments in producing pictorial images on glass, rendered sensitive to the action of light, and he may have heard that among the occult processes essayed at the wonderful laboratory in Soho by Matthew Boulton, the illustrious partner of James Watt, was one for copying paintings and natural objects by means of the sun's rays focused through a lens on to a sensitive surface. Of Lord Brougham's claim to have invented photography, Mr. Fox Talbot was probably ignorant, for the assertion was only publicly made in Brougham's posthumous published autobiography; but the discoverer of the Talbotype was aware that Sir Humphrey Davy had revealed early in the century his observations on Wedgwood's experiments, and that in 1827 the distinguished Frenchman, Niepce, had made known in

London his experiments in a similar direction. Six years afterwards Mr. Fox Talbot, happening to be sketching the scenery of the Lake of Como, and availing himself of that fascinating but delusive toy, the camera-lucida, as a mechanical assistant, fell to thinking whether it might not be possible to render permanent the fleeting images cast on the pages of his sketchbook by the camera. He thought and thought and experimentalized incessantly, when, just as he deemed that he had brought his cogitation to a successful issue, read in a foreign scientific journal that a certain Frenchman, named Daguerre, had arrived at a discovery analogous to his own. The pictures of the Daguerreotype were, it is well-known, produced on thin silvered metal plates. Mr. Fox Talbot's medium was paper, and in 1839 he communicated his invention to the Royal Society, of which he was a member. Consistently modest, he desired to term the process "photogenic drawing," or "calotype"; but the large-hearted Sir David Brewster insisted that it should be called the "Talbotype." Subsequently, all the processes were merged in the wider appellation of photography. At least in this case neither the distinguished Frenchman nor the illustrious Englishman was insidiously robbed of his glory. A compromise was effected, and Light, the parent of the entire discovery, got all the honours. There was no mediocre Amerigo Vespucci to slip in and filch the fame of the Columbus and the Magellan of the New World of graphics. Of course—it was in 1842—Mr. Fox Talbot thought of taking out a patent to compensate himself in some measure for the discovery which he had undeniably and independently made, that sensitive paper during its exposure to the light receives an invisible image, perfect in all respects, and that, in order to render the image visible, it is sufficient to wash the surface of the paper over with gallic acid, or some astringent liquid. But, on reflection, he nobly determined to forego all prospects of profit from his invention, and gave it up unreservedly to the world. In after years he communicated to learned societies at home and abroad the upshot of further investigations into the process of obtaining instantaneous photographs, and the application of his beloved art to engraving on steel. He was an erudite linguist, too, an antiquary, and a cryptologist, and he went on until the end, still acquiring fresh knowledge, and using it, as he had always done, for the benefit of mankind. Fortunately, he was a wealthy country gentleman, without pride, save in that which was good, without ambition, except to serve his fellow-men. He was happily preserved from the indifference of governments and the ingratitude of the mob, although but for the favour of fortune the discoverer of the Talbotype might probably have added another name to the long list of benefactors to their species who have passed their lives in penury and neglect, to die in a garret.

That photography has been an unmingled boon to civilisation it might be difficult to prove. It has been turned occasionally to villainous uses; and, even when considered in its aspect as a hand-maid to art, there may be those who will contend that photography has often shown itself to be an evil counsellor, distorting and exaggerating those very features of nature which, ostensibly, it so unerringly depicts, dulling the painter's fancy, and luring him to slavish adherence to the most prosaic and debasing realism. Could a Raphael or a Michael Angelo have flourished in the presence of photography? Would the works of Titian and Velasquez have been so eagerly sought for if their age had furnished "life-sized photographs" and "album portraits"? All these may be moot points; yet does it seem incontestable that the few drawbacks which may be alleged as marring photographic perfection are more than compensated by the immense amount of social benefit which it has conferred on the world at large. It may be argued that the cheap and inexhaustible resources of photographic printing have paralyzed the art of steel engraving, and killed lithography so far as that art is pictorially employed, and that even wood engraving and typography are not definitively safe; yet, on the other hand, to how many millions has not photography been a convenience, a comfort, and a blessing? The benignant camera is as much the friend of the poor cook-maid as of the crowned head. It will distribute as sincere smiles for sixpence as for ten guineas. It can scarcely have conducted to the enhancement of national vanity, for photography never flatters, and rather amplifies than diminishes our personal defects; but it has been a sure and constant foster-mother of the domestic affections, and, equally with penny postage, it has been the means of strengthening family ties, and alleviating the sorrows of absence. A shilling carte-de-viste travels the whole world over. It is the bringer of good wishes, the harbinger of good news, the remembrancer of old loves. Photography multiplies for an entire household, and for their remotest kindred and friends, the images of the children

in whom we rejoice, and of the dead whom we revere. If the wonderful art had done no more than this, its services as a factor in civilization would still have been stupendous. But it has done much more. Medical, astronomical, botanical, archæological science owe an enormous debt to photography. The traveller, the *savant*, the anatomist, the geologist, the manufacturer, the tradesman, the officer of justice, even as he pursues his prey, are all fain to avail themselves of the camera's assistance; and there is scarcely a department of human knowledge, or an occupation of our daily lives, in which the development of the old Talbotype is not a most valuable adviser, assistant, and expositor. It is, in short, an art as full of grace as of utility; and its discovery, without rebelling Wedgwood, or Boulton, or Brougham, Niepce, or Daguerre of one loaf of their laurels, must shed undying lustre on the name of Fox Talbot.

AN IMPROVEMENT IN THE CAMERA FRONT.

BY M. NOTON.*

I EG to submit for the examination of the members of this Society a substitute for the usual slit in the camera front fitted to my rectangular camera, and giving any amount of motion, limited only by the inside of the camera itself. It is perfectly light-tight, very simple, and, although it looks a formidable affair on paper, it is applicable to any size of camera, however large.

The utility of the ball-and-socket mount was checked by the old slit, so there was nothing left but to contrive something better. Now all is clear, and no one need be bothered with the old state of things any more.

The accompanying sketch will, I hope, give an idea of

the arrangement. The left-hand drawing is an elevation, the right-hand one being a plan.

1 represents part of the sliding front.

2 is a round iron rod fixed inside the camera near to the inside face of the sliding front, down towards the bottom and under the lens or up towards the top of the inside, either way. The sliding front has a hole cut through it by a centre bit, midway from each end; this is to allow a brass ferule (3) to pass through to carry the front. This ferule is continued on towards the rod 2. Through the ferule a small wrought-iron eye bolt (5) passes, the left hand end having an eye through which the round rod (2) moves easily; the right-hand end is screwed and furnished with a milled-headed nut (4).

When the nut 4 is screwed up tight it presses against the end of the ferule as an abutment, drawing up the eye-bolt, and with it the rod, against the left-hand end of the ferule; and so, between the two the rod is gripped fast, and the front supported by the ferule, without there being any strain upon it.

In the camera exhibited the rod 2 is eight and three-eighths inches long by one-sixth of an inch diameter, its weight being 329 grains.

The eye bolt, ferule, and nut weigh only 183 grains; the whole apparatus having a (very) gross weight of 512 grains, or just thirty-two grains more than an apothecary's ounce.

* Read before the Manchester Photographic Society.

ON THE USE OF THE ACTINOMETER WITH DRY PLATES.

BY J. H. T. ELLERBECK.*

THE great uncertainty in judging the actinism of light at different times and in different situations has always been a drawback to the use of dry plates in the field, resulting often in under-exposed pictures. We find frequently the prettiest "bits" are in more secluded spots, where much light is lost—how much we could only guess at—wooded glens, deep ravines, trees in the forest, and water-falls, with rocks black with lichens hidden frequently from the light of the sun. How very seldom do we see these correctly timed! I look back with longing regret to hard and worthless attempts of former days, when all was guess-work. Though I often fail now to get good pictures, it is from other causes—such as want of sharpness, and that great bane of photographers, a windy day, with nothing but foliage to do. When, therefore, a correspondent in the *British Journal* suggested the actinometer its value at once struck me, and its use as a move in the right direction. To advocate and explain its use to amateurs is the object of this paper.

The actinometer I use is one issued some years ago by the Autotype Company in connection with carbon printing, and consists of a metal box about one and a-quarter inch square, containing a roll of sensitised paper, which is gradually drawn out. Under a glass lid painted purplish brown, with the exception of a central slot through which the paper is seen, the paper deepens in the light until it assumes a colour similar to the paint around. This is known as a tint.

In ordinary summer sun, using Durand's paper, this takes place in 45 seconds. If, therefore, under other circumstances, it requires more than this, we know the relative strength of the light, and the exposure in the camera must be altered in proportion. Thus, under similar conditions of time and light, a washed collodio-bromide plate, with Ross's rapid symmetrical lens, No. 1 stop, takes 90 seconds. When one tint equals (say) 68 seconds, the exposure necessary is 135 seconds. Practically, I say, such a lens, stop, and plate take two tints, and, if I expose plate and actinometer at the same time, I must register two tints; thus, it does not matter whether the sun shines, or whether the rain comes down in torrents. On the mountain top, by a wooded river, indoors or out, so long as the actinometer registers one tint twice, I know all is right. If No. 2 stop be employed, one tint only is sufficient; if No. 3, half a tint; and if full aperture, a quarter of a tint. If either of the two latter, the time must be known before the exposure commences. If a whole or more tint is given, the two exposures may go on simultaneously. With other lenses and plates different exposures are necessary; each must calculate his own. Supposing, for instance, you would usually give five minutes with a certain stop; this is about equal to seven tints, and so on.

If the exposure is to be more than one tint, it (the measurement) had better go on together to the end. The varying light of a cloudy day is better managed than by simply multiplying the time of one tint as a guide for the remainder. Thus, the first tint may occupy three minutes and the second only one, if the sun breaks away from the clouds. The only objection I have ever heard against this method is that you cannot always place the actinometer in the same strength of light as the subject photographed. I think you can—in most cases at least, and if you cannot it is surely a poor reason for discarding a valuable aid because you cannot under every circumstance avail yourself of it.

But, of course, judgment must be used in its employment. If the subject be in shadow it would be absurd to

put the actinometer in the full glare of the sun. If the camera be in shadow, and the subject an open landscape, the actinometer must go out too. If light is strong it is easy to measure it beforehand, and if weak you will have ample time for walking to and fro from shade to light. There may be cases of insurmountable difficulty, but I have never met with them. The camera itself, or one's own body, will give shadow if this predominate in the picture. One of the last pictures I secured was of a path through the woods, trees overhanging, and the sun behind—a difficult subject, for the camera was in the open facing the sun, which shone on the lens. Shading this, and placing the actinometer at the back of the camera, I gave three tints instead of two, and the result was good. I do not argue that the instrument is automatic. Open, distant landscapes and snow scenes will still take less, and dark, heavy foliage always more, in proportion to ordinary objects. The judgment is helped, not dispensed with.

I have said that one tint is equal to forty-five seconds; this is in the sun, as we in this cloudy, smoky part of England, are accustomed to see it. But on a bright day, in the clear mountain air, I have found thirty seconds was enough, and in other climes even less might do. I remember a remark made lately by one of our members to the effect that in Italy one-half the exposure was given of that necessary in England. By the use of the actinometer all doubt would be at rest. Thus I have noticed a February sun wants two or three minutes; a September sun, at one p.m., two and three-quarter minutes, and at six p.m. ten minutes to form a tint. One cloudy day the light was so weak as to want fifteen minutes, and another, late on in the afternoon, twenty-five minutes. In a chapel, where I tried it lately, I do not think a week would have done it.

Take care always to use the same sensitive paper, as papers vary. I lost some pictures lately from having to beg some from a stranger, having run short of my accustomed Durand's make, and found afterwards it was much more sensitive, though it would not keep a week.

On a windy day an advantage is frequently gained by being able to cap and uncap the lens and actinometer at the same time, at intervals of rest in the foliage, without fear of losing count of time. Lately I adopted this dodge in taking an old house in a narrow street. By this means I escaped the blurs of passing carts and inquisitive Welsh children, who, not being open to reason, could not be driven away.

Of the actinometer itself little can be said. It is not a convenient shape, but is thoroughly efficient, being light-tight and almost air-tight, thus keeping the paper fresh. Those who use gelatine plates would like to register half a tint, and one could easily be made by altering the colour of the paint on the glass lid. A thinner instrument would be handier for the pocket. The Autotype Company make another form more elaborate for carbon printing, showing tint exposure from one to ten. This would be of value only to those who use the slow and sure processes, such as collodio-albumen.

I hope these few rambling remarks will induce amateurs to adopt the method recommended. I feel certain that if once tried it would never be abandoned. It is so easy and so certain, giving no extra trouble, and incurring no expense beyond the cost of instrument (two shillings and sixpence), all anxiety is done away with, and failure from wrong exposure almost impossible. I know that old members of the fraternity will say it is of no use, and that they can calculate the time by the appearance on the ground glass. Still, all amateurs have not the requisite experience, and a safer guide than memory is often desirable, even with the most practised. No one prints in carbon without such a guide; yet, if the results were not good, it is but the loss of a print. Why, then, risk the loss of what might be a valuable negative, which, perhaps, could never be replaced?

THE INVENTOR OF THE CALOTYPE PROCESS.

THE death of Mr. Talbot has revived, in some degree, the controversies which at different times arose as to his true relation to the discovery of photography. In M. Tisandier's very excellent history of photography, published some time ago, Mr. Talbot's claims to the title of inventor of the art are dealt with in a summary and cavalier fashion. His discovery is pronounced "not practicable," and it is stated that it had not "the good fortune to attract the attention of the learned world." A curious statement, when it is remembered that Mr. Talbot received for it the gold medal of the Royal Society of England. The chief value which it is allowed by the French author is, that it served as a ground-work for the labours of Blanquart-Evrard, who gave it "certainty and facility of working." It was generally acknowledged," M. Tisandier observes, "that the mirror-like character of the Daguerreotype plate was incompatible with a really artistic picture; it was thought, with reason, that a proof on paper would be softer, and would resemble a sapia drawing. Thus, as soon as Blanquart-Evrard, of Lille, published his method, his communications were received with expressions of joy by all photographic amateurs." Although the "Daguerreotype seemed to have the sole right to occupy the attention of Paris," and Talbot's invention was unrecognized, yet the need of photography on paper was recognized, and when Blanquart-Evrard had made the method practicable it was hailed with joy! As we shall shortly be in possession of Mr. Talbot's reply to these statements, it is scarcely necessary to refute them here. In a second edition of M. Tisandier's work, which we are glad to hear is about to be issued, Messrs. Sampson Low and Co. will publish an appendix by Mr. Fox Talbot, giving a history of his early labours in the production of sun pictures. One word on the practical character of the process may not, however, be out of place here. Those who are familiar with the early Talbotype pictures need no assurance of the practicability and excellence of the process. We recently examined a photogenic drawing produced within a few days after first hearing Mr. Fox Talbot read his paper describing the process. This print was still preserved in the small, improvised frame in which it was printed from a piece of lace edging as negative. The print was clean and bright, of a brown tint, having been fixed with bromide of potassium. This was the first photographic print of one who subsequently became one of the very ablest photographic amateurs, Dr. Diamond. No proof could possibly show more conclusively the excellence and practicability of this process than that which has come under our attention in the shape of something like five hundred calotype negatives, ten by eight inches in size, each

as so perfect in definition and in all points of technical as well as pictorial excellence, as to render the examination of them an absolute treat to an educated photographic eye. When we remember, also, the early Calotype landscapes of B. B. Turner, Alfred Roslyn, Llewellyn, and many others, the old masters of photography, and recall to mind the grand series of Calotype portraits by Hill and Adams, which live in the memory of many photographers, we cannot for a moment admit that the process lacked either excellence or practical character. It is true that the inventor was indebted, as many other inventors have been, to the experimental effort and artistic and technical skill of an army of enthusiastic amateurs, for giving value and currency to his discovery, by showing what bright things it was capable of producing. The real basis of a depreciatory estimate of Mr. Talbot's claim arises in the question as to how far he was the actual discoverer of the existence of the latent image on paper, and the use of gallic acid for its development, which careful investigators attribute to the late Rev. J. B. Reade. Daguerre had discovered, by happy accident, the existence of a latent image on the iodized silver plate. By accident, also, Mr. Reade had discovered a similar fact, when using silvered paper in conjunction with an infusion of galls, some time anterior to the date of Mr. Talbot's patent. Sir John Herschel had used iodide of silver. But the philosophical mind of Mr. Talbot saw the significance of all these things, and produced and patented a perfect practical process.

Mr. Talbot's step in protecting his process has been the subject of much challenge. Some have denied his right to patent that which was the partial discovery of others. Many more have questioned his wisdom and good taste, as a wealthy man and votary of science, in thus attempting to lock up such a discovery by patent. The *Athenæum*, in a notice we print on another page, thinks it was unfortunately and unwisely done. Probably it would have been better for his fame, and no worse for his pocket, if he had at once given his discovery to the world. But we are by no means assured that the public and the process are always gainers by such a course. The direct interest of one proprietor in the commercial results of a process is often the surest guarantee of that process being worked out to its best issues, which, if it be the general property of many, is by no means certain. A piece of land forming the garden, orchard, or field of a proprietor is generally well cultivated. A similar piece consisting of common land, where all may gather the produce, is rarely cultivated at all. The *Standard*, in a notice we also reproduce, says either in irony or curious ignorance, Mr. Talbot "thought" of patenting his process, but "on reflection nobly determined to forego all prospects of profit from his invention, and gave it up unreservedly to the world." That Mr. Talbot did not take this course is now notorious to the world. Ten years after the date of his patent he gave it to amateurs, still reserving, probably not altogether unnaturally, his right in its use for professional portraiture. A year or two after that he took steps to secure a renewal of his patent, a course not, however, carried out. In the meantime the case famous in the memory of photographers of Talbot v. Laroche was heard and determined. Mr. Talbot wished to enforce his patent on all portraitists using collodion, on the ground that they used iodide of silver to obtain a latent image, and developed it with pyrogallie acid, which he considered to be protected by his patent, on the score that pyrogallie acid was a sufficiently near equivalent of gallic acid, and a collodion film a sufficient equivalent for paper, to be covered by his patent. He failed in substantiating his claims to the satisfaction of a British jury, and henceforth photography was open to the world.

Mr. Talbot's engraving process, which he also patented, was at that early date a great advance on what had been done, and the specimens which we gave in an early volume of the *Photographic News* will bear examination at the present day. The final invention of Mr. Talbot, which

was also patented, has never, we think, been sufficiently worked out, nor have its suggestions been sufficiently utilized. The subject was instantaneous photography, and the results obtained were very remarkable. A printed paper was fastened to a wheel, which, being made to revolve as rapidly as possible, was illuminated for a moment by the discharge of a Leyden battery. The bill thus illumined by a momentary spark was perfectly reproduced, without blur or imperfection. The method, briefly stated, was as follows:—A plate of glass was evenly coated with equal parts of albumen and water, and dried by heat. It was then dipped into a three-grain solution of nitrate of silver, the solvent being a mixture of alcohol and water. It was then washed in distilled water, and again, when dry, coated with the albumen solution, and dried without much heat. It was then dipped for a few seconds in a solution of photo-iodide of iron, made as follows:—To an aqueous solution of the iodide add an equal quantity of acetic acid, and then ten volumes of alcohol. This must stand for a few days, during which time it will change colour and lose the acid and alcoholic smell, acquiring a vinous odour. It is finally rendered sensitive by immersion in a bath of aceto-nitrate of silver, containing seventy grains of the silver salt in an ounce of water to three parts of the solution, two parts of acetic acid being added. It is then exposed in the camera without delay. The latent image is brought out by an iron developer containing one part of a saturated solution to two or three of water. The image is rapidly developed: fixing with hyposulphate and washing finish the operation. At the conclusion of Mr. Talbot's account of this process he remarks that it consists of "the harmonious combination of several previously-ascertained facts" due to former discoverers; and that the value of the process chiefly consists in the due adjustment of the proportions and in the mode of operating; and adds, that a very slight deviation will not only destroy the exalted sensibility, but often yield scarcely any result at all. The last sentences convey a truth we commend to many thoughtless photographers who try a process imperfectly, and then blame upon the originator or expositor the results of their own failure.

PHOTOGRAPHY AT THE AMSTERDAM EXHIBITION.

WE are favoured by an old and esteemed correspondent, Herr Haakman, with the following interesting details of the Exhibition in Amsterdam, which, it appears, is a decided success:—

Amsterdam, September 21st.

DEAR SIR,—I have the pleasure to write you a few details about our International Photographic Exhibition, which opened last Tuesday, and was visited the following day by H.M. the King and his brother, Prince Henry. I am glad to say our Exhibition is considered a great success. It is held in the galleries of the Art Painters' Society, "Arts, Amicitia"; and as for the hanging of the frames, we had the assistance of a committee from the said painters' club. The different rooms present a really artistic appearance. Our catalogue comprises about fifty contributors, American, Belgian, English, German, Russian, Scotch, Dutch, &c. England is represented by Messrs. David Hedges, J. M. Browning, Hare, S. Fry, &c.; America by Gutekunst of Philadelphia, Kocher of Chicago, and Notman of Canada; Russia by Bergamasco; Belgium, by A. Dandoy; Namur, by A. Cadot; Brussels, by P. Halley; Dinant (Germany), by J. B. Frilner; Bremen, by Geldmacher; Frankfurt-on-Maine, by S. Kiewning; Stettin, by Herman Koch; Waldenburg in Silesia, by Carl Metzner; Coburg, by T. Muller; Munich, by Reichard and Lindner; Berlin, by Martin Kommel; Stuttgart, by Baron Stillfried; Austria, by Taeschler, &c.

As the jury meets on October 4th, and I am one of them, it is perhaps premature to enter into any details as

to the merits of the respective exhibitors; but in my (and I believe the general) opinion, Kocher of Chicago stands first for his portraits, each of which is a perfect gem. Each portrait is a genre picture, and our artists and painters are quite in raptures over them; in fact, there is quite a revolution in photographic portraiture, and totally different from anything I ever saw.

Gutekunst has one frame containing a panorama about six feet long, of the Philadelphia Exhibition Grounds. This said picture was printed from six different negatives on one continuous sheet of paper, but the printing is so well done, and the tone so well kept up, that it is almost impossible to detect the joining. The price asked for this picture is \$200, about £15.

I forgot to mention a large collection of really magnificent landscapes, water-falls, tree studies, dead game, &c., by Mr. Penn, of Ootacamund, British India. In fact, we liked them so well that, although they were sent unmounted, we mounted and framed them at our own expense, as a just contribution to their merits.

If you are agreeable, I shall send you some further details after the jury have made the awards. When there is so much excellence, it is quite impossible to do justice to everybody in a few rapid lines, and I only wish to give a cursory glance at what is, to speak, beyond competition. Every photographer should come to see Kocher's pictures. It will be money well laid out, and paying more than its interest.—Believe me, dear sir, very truly yours,

H. L. T. HAAKMAN.

PORTRAITS IN OIL FOR THE MILLION.

UNDER this title Mr. Solomon is introducing something old enough to constitute one of the greatest and most interesting novelties of the day in connection with photographic portraiture. We have had occasion very frequently of late to notice the methods, often rediscovered, often patented, of colouring photographs at the back, first, of course, rendering the photographs transparent. The principle is a simple one, and, on the very face of the subject, a correct one. It differs from the ordinary method of colouring in the fact that the photograph is superposed upon the colours, instead of being covered up with colours laid on its surface. The principle was, as we have frequently explained, one of the earliest discoveries accessory to photographic portraiture; it has been often patented, and for some strange reason has never come into general use. The probable cause is that, simple as the method seems, it requires some experience for its successful application. Mr. Solomon has recently called our attention to some very admirable examples, and undertakes to do similar work for the "trade," on very reasonable terms. He does not, as he explains, profess to have made any discovery, or introduced any great novelty. He finds a good and simple process in existence which is not generally understood; he undertakes to master its peculiarities, so as to work it well; and, this done, he offers to carry out the work for photographers on terms which will, he thinks, pay portraitists, and enable them to place in the hands of the million of limited means a portrait of excellence, only accessible hitherto to the wealthy. This is the real novelty—the facility for portraitists in any part of the country to obtain high class oil painting in connection with their portraiture on terms hitherto charged for the poorest daubing. The examples we have seen are exceedingly well done and very effective. The likeness, as regards drawing, must be good, as it is simply the photograph itself; the accuracy of colours must depend somewhat upon precision of description. The style is solid and good, with nothing of a common effect. The prints are mounted on canvas, and varnished and mounted in a capital solid gilt frame, at the low price charged, so that the photographer has no trouble whatever. He sends off a good print, and receives back a

fine oil painting, ready for delivery to his sitter. The project deserves success, and will, we doubt not, attain it. Mr. Solomon will have done a good work if he succeed in supplanting many of the common, inartistic daubs which a love for colour aids in carrying into the houses of the uneducated and poor.

THE WARNERKE TISSUE FOR MULTIPLYING NEGATIVES.

We have already referred incidentally to the employment of the Warnerke tissue for the production of transparent positives, and we desire now to say something of its adaptability for multiplying negatives. A rapid method of turning one negative into a dozen must be valuable to all photographers, and in some cases it is only by having such a method at one's finger's ends that it is possible to derive profit and advantage from a cliché in our possession. A great personage who consents to sit for his portrait usually requires that the operations of posing and exposing shall be done in the briefest of intervals, for his time is valuable, and he can give up but a very small portion of it to the photographer. The latter, therefore, can never hope to secure more than one or two favourable clichés, and these must be valued accordingly.

Or, again, when chance or good luck has put us in possession of a plate, the value of this is often confined when we cannot take full advantage of it. The case of the negative taken by a passing travelling photographer of M. Thiers the day before his death is a very good instance of this. Here is a negative of a great man whose name is in the mouth of every-one, but the importance of which (the negative we speak of, and from a commercial point of view) must diminish by the day, nay, by the hour. If the lucky photographer to whom we allude had possessed no ready means of multiplying his single negative, the value of this would have been represented in the main by the number of prints that would be struck off in a fortnight or three weeks. But as he was enabled to produce from his original a large number of duplicates, the value of the former was at once enhanced, and it has realized its happy possessor, we are told, quite a little fortune.

Some experiments we have made with the Warnerke film demonstrate that this material is exceedingly well adapted to the multiplication of negatives. The first thing, of course, is to produce a transparency, and the film employed for the purpose need not to be so highly sensitive. The soft pliable material is treated as if it were albumenized paper, only greater care is taken to keep it sheltered from light. The tissue is laid upon the negative, and printed in the ordinary manner in a printing-frame. It matters little what exposure is given. Half an hour will not hurt, but one or two minutes are of course ample. On taking the film from the pressure-frame the image will be perfectly visible, and on application of the ordinary developer a vigorous positive picture is rapidly evolved. The intensity of this can be governed with much ease. From this positive negatives are printed in exactly the same way, and the circumstance that the tissue is soft and pliable invariably insures contact and the rendering of every detail. When we mention further that the development, fixing, and drying of these over-printed films is so rapid that in a couple of hours half a dozen negatives may be produced, nothing more need be said upon the facility with which the various operations can be carried out.

In conclusion we may say that positives of Warnerke tissue make famous transparencies for the lantern.

NOTE ON EMULSIONS.

BY M. CH. BARDY.*

I ask the permission of the Society to communicate the results of some experiments I have made upon the inter-

* Read before the French Photographic Society.

esting emulsion process of M. Chardon. It was my desire to render the preparation of the emulsion more easy when operating with relatively large quantities of the material, and at the same time to arrive at a more perfect division of the bromide of silver.

The agitation of the products together is beset with but little difficulty when it is only a question of producing some grammes of material; but it is different when you desire to make several litres of emulsion at one time. In this case the shaking together of the ingredients is a difficult and laborious operation. To remedy matters, I had recourse to a little apparatus constructed by M. Alvergniat, of which below is a sketch:—

Upon a flat rod of iron, A, 60 centimetres long, 3.5 wide, and 1 centimetre thick, are rivetted at right angles two rods of iron, B B, at 1.5 centimetre in diameter, and 35 centimetres long, with spaces between them measuring 45 centimetres. The whole is fixed into a wall. On each of the rods is placed an iron ring, C C, provided with a screw, which serves to hold fast the ring at any point of the rod. Each of the rings, or, rather, clamps, has attached an iron rod, D D D D, 85 centimetres long, terminated at the bottom with a sort of eyelet. The four rods, D D D D, serve to support a little board of oak, E, 55 centimetres long and 20 broad, with supports, F F, so placed as to receive a bottle and fix it in a horizontal position. The whole system forms an articulated parallelogram which obeys the slightest movement.

If a to-and-fro movement is given to the frame the bottle moves forward and backward in a straight line, and thus the liquid contained is vigorously agitated.

This movement may be imparted very easily by having recourse to a little water-engine constructed on the Schmidt system (the model employed for sewing machines), and which has a power of a few kilogrammes only.

It can be readily understood that a small power only is required to set the apparatus going, and to shake up several kilogrammes of liquid, all the weight being supported by the eyelets at C C. The Schmidt machine works day and night without requiring to be watched; the greater and more continued the agitation, the more perfect will be the resulting product. The same apparatus may be employed for redissolving an emulsion in alcohol and ether.

I myself have operated with several litres at a time, and my emulsion leaves nothing to be desired. I may say, however, that, acting upon the suggestion of M. Andra, I introduce the bromised collodion into the warm alcoholic solution of nitrate of silver, without occupying myself about the precipitate that is formed.

The precipitation of the emulsion with warm water I am enabled to bring about without difficulty. I may mention that it is only necessary to press the precipitate moderately; in order to hasten desiccation I have sometimes, indeed, put it under a press. But the result has never been so satisfactory as with the same emulsion simply drained and dried.

To render desiccation more rapid, and, at the same time, more complete, I allow the precipitate to remain upon blotting-paper; I put it under a bell jar upon an air-

pump, and, having placed under the same protection a vessel containing sulphuric acid, I proceed to exhaust the air. The product resulting from such an operation is flocculent, dissolves rapidly in a mixture of alcohol and ether, and furnishes a very delicate film, exempt from all defects.

The operation of drying may, however, be avoided by introducing the precipitated emulsion, while yet wet, in a bottle containing alcohol at 40° Cent. At the end of a few hours the whole is turned out upon a cloth, the precipitate is gently pressed, and then put again to digest in concentrated alcohol. This second bath is for the purpose of eliminating the last traces of water; you drain as before, and the emulsion may be at once dissolved in an alcohol and ether mixture. The litre of collodion, according to M. Chardon, furnishes fifty grammes of perfectly dry emulsion. I recommend this modification in its preparation, for the clichés produced are purer and more brilliant.

If it is preferred to preserve the emulsion in the form of a dry powder, that treated with alcohol will dry more rapidly, and will be found to be in a very favourable state of division for redissolution.

In conclusion, I may mention that during the great heat of the past summer I was compelled to modify in a slight degree the proportions of alcohol and ether indicated for re-emulsion. I employed sixty per cent. of alcohol and forty per cent. of ether. This modification appeared to me necessary in order to avoid a fleeciness which was visible in the collodion when equal parts of alcohol and ether were employed.

So far as I am concerned, I have nothing but praise for M. Chardon's process; the manipulations are simple, and free from all useless complications, and by following exactly the directions laid down, you are sure to secure a successful result.

PROGRESS OF HARDENED GLASS MAKING.

ABOUT two years ago M. Royer de la Bastie produced his tempered glass. It will be remembered that the Bastie process consists in heating the glass object to a red heat in a furnace, and plunging it while in this state into a cooling bath. This method, in common with some others of later date, and based on the same principle, requires that the object shall be completely formed before the hardening operation, and this, besides producing other disadvantages, tends to enhance the cost of manufacture. The glass, when heated to the necessary temperature, becomes so softened that it is almost impossible to transport the object from furnace to bath without some deformation taking place, and to this cause are due the irregularities so often noticeable in tempered glass articles, and notably the departure of window panes from a true plane. There are other disadvantages due to the bath, which is composed of oil or other greasy material heated to a temperature varying between 392° and 572° Fah., according to the quality of glass to be tempered. When the red hot article is plunged in, the oil easily takes fire. This can, of course, be avoided by proper precaution, but it is obviously a source of danger. There are, besides, the disagreeable odour arising from the bath, the large expenditure of oil, which decomposes on contact with the hot glass, and finally the fact that each special composition of glass requires a different temperature of the bath, and it is very difficult to maintain exactly this temperature during the operation. It will thus be clear that in the bath is the weak point of M. de la Bastie's process.

Herr F. Siemens, who has devoted considerable attention to the Bastie plan with the hope of overcoming some of its practical difficulties, appears to have become convinced that the invention is inapplicable to the fabrication of certain forms of glass, among which are included window panes. To these last any hardening process probably finds its most important application. After some experiment

Herr Siemens reached the conclusion that solid bodies, or rather moulds, could be substituted for the cooling bath. His first attempts, made with the object of hardening small squares of glass between plates of baked earth, showed clearly that the idea was practicable. This was eighteen months ago, and during the subsequent interval up to the present Herr Siemens has achieved constantly improving and successful results.

The *Deutsche Industrie Zeitung*, whence we take our facts, states that the method of fabrication of the compressed glass is not merely a glass-hardening process. It constitutes at the same time a veritable method of glass making. Tempering, blowing, and moulding are all accomplished in one and the same operation.

It will be perceived, however, that all objects in glass cannot be made by this process, and that its application is restricted to such as can be pressed between two simple forms. To this category, however, belong window panes, to which at present Herr Siemens proposes to restrict his manufacture. In brief, the Bastie and Siemens methods may justly be regarded as each having its peculiar sphere. Bastie's plan is especially suited for cylinders, hollow glass, and other articles of complicated form, while Siemens' system, as already stated, is best applied to simple figures. The resistance of the Siemens glass to shock is stated to be ten times that of common glass, but its cost is about 50 per cent. higher, except in case of curved window panes, when it is the cheaper. It is said to be harder than other tempered glass, and to present a fibrous instead of a crystalline fracture. It may be polished or pierced without the rupture which occurs in the Bastie glass. Herr Siemens is engaged upon still further improvements, which it is believed will tend to decrease the cost.

At the Lyons Industrial Society, recently, M. Leger proposed tempering bottles and similar glass objects by steam. The tensile resistance of the glass thus prepared, he states, is about equal to that of cast iron. No details of the process are given.—*Scientific American*.

WATERPROOFING PAPER.

AMONGST recent patents which may interest photographers, are three by Mr. Daniel Felton, of Manchester, for rendering paper waterproof. The first process consists of the treatment of the tissue to be waterproofed with chloride, sulphate, or other soluble salt or salts of zinc or cadmium, in conjunction with ammonia, applied in the form of a solution composed of about three parts of crystallised sulphate of zinc, or three parts of a solution of chloride of zinc at 96° (Twaddle), and about two parts of solution of ammonia of specific gravity 875. The paper or cloth which it is proposed to treat is passed through a cistern lined with lead, and specially constructed for this purpose, with an arrangement of rollers, so as to allow the material to pass through at a speed varying from thirty to thirty-six yards per minute, according to the thickness or thinness of the substance at the time under treatment. In its passage through the liquor with which the cistern or bath is charged, the material becomes perfectly saturated and impregnated. From the bath the saturated material passes through a pair of squeezing rollers, which remove the superfluous liquor, and harden by compression the substance submitted to treatment. From the rollers the material is next passed to a suspending apparatus, then hung along the room in folds in a temperature of 110° (Fahrenheit) until it is sufficiently dry to be taken down. The rollers in the cistern, the squeezing rollers, and the suspending apparatus are so speeded that the material is taken from one to the other without any inconvenience or stoppage.

The second process is a treatment with glue, gelatine, or other similar substances, in conjunction with bichromate or chromate of potash, soda, or alumina, applied in the form of a solution of about one part of glue or gelatine

in about eight parts of hot water at 160° (Fahr.), and a solution of about one part of bichromate of potash in about fifteen parts of water, or a solution of the before-mentioned bichromates or chromates in the same proportions. The mode of treatment in this case differs from the former only in two points:—1st. During the time the material is traversing through the bath, as already described, the solution is maintained at 160° Fahr. by means of siphon pipes charged with steam. 2nd. Instead of suspending to dry, the material is immediately passed over three steam cylinders seven feet in diameter, carrying a pressure of fifteen pounds to twenty pounds to the square inch. The cylinders are provided with gauges to indicate the pressure they are required to carry, and also with safety-valves to prevent this pressure from being exceeded. Although the bath is always in a state of darkness, yet it is specially necessary in this case, for without this the process of waterproofing the material by means of chromates or bichromates could by no possibility be accomplished.

"3rd. By treatment with acetate, sulphate, or chloride of alumina, applied in the form of a solution of about one part of any of these compounds in about six parts of water at 160° Fahr. The same conditions are required to produce a waterproof material with these compounds as those described above, with this difference, that it is not absolutely necessary to preserve darkness during the process. The claim of the patentee is thus worded:—

"Each of the foregoing processes I claim as my invention for the production of waterproof paper, cotton, or linen cloths, or other ligneous tissues. Paper and cloth may be taken together, through the treatment which, by its adhesive nature, binds the two together—thus giving a durable, pliable, and impermeable material suitable for any purpose where immunity from damp and moisture is required."

If the paper employed for silver prints could be made waterproof, it is probable that such an operation would tend towards permanency, and it is not improbable that a modification of some of the processes above described might be rendered available.

Correspondence.

LOCALIZING DEVELOPMENT IN CARBON PRINTING.

SIR,—By the following simple method I have succeeded perfectly in localizing and accelerating the development of carbon prints, and I now use it in daily practice. The method is as follows:—

I take a small piece of very soft wash-leather and wrap it round the finger; then dip it into a cup of warm water to which a few drops of ammonia have been added; then gently rub the portions of the carbon print that appear too dark and lacking in detail. For instance, it sometimes happens that the hair appears too dark and lacking in detail (especially in a Rembrandt picture), whilst the face and lighted portions are everything that could be desired.

Now, by adopting the method I have described, I find it possible to bring all the detail out in the darker portions and shadows, whilst the lighter parts are not in the least degree affected.

It is also a very rapid and easy method of reducing a rather over-exposed print, and by using the water hotter or colder, as the case may be, you have perfect control over the result. I find that it also cleans the surface of the tissue from all specks or dust that are liable to become attached to it from the washing-water or other causes, and which are very difficult to remove by an ordinary stream of water.

It is astonishing what an amount of friction the tissue will bear with the moistened wash-leather without in the least degree injuring the surface.

Should you think it worth while to give this a place in the columns of your valuable periodical, you are at liberty to make what use you like of it; if not, consign it to the waste-paper basket.—Yours obediently, THOS. B. LATCHMORE.

AMATEUR PHOTOGRAPHY IN THE WEST INDIES.

DEAR SIR,—Do you think the following worthy a corner in your valuable publication? I have been dabbling in photography, off and on, for the last twelve or thirteen years. When I commenced I found great difficulty in obtaining a correct focus. I removed the lens, and with a rule measured the distance from the lens aperture to the focussing glass; I then put in a plate-holder with a glass and measured, but found the distances did not coincide. To remedy this I adopted the following plan, and have had no difficulty since:—I take a plate and gum over it the thinnest and finest tissue paper I can get; when dry, I rub it with a little oil. This makes a capital focussing glass. When I wish to focus an object, I put this into the plate-holder and focus from it. When I afterwards insert the sensitized plate it necessarily occupies the precise place as the focussing glass. I enclose two views, one of Hope Vale Sugar Works, the other of part of the Carenage with Government House in the distance; and I think you will admit a want of sharpness is not one of the many other defects. The views were taken some years ago, and have been recently printed upon plain salted paper. The exposure was about eight minutes, with $\frac{1}{4}$ inch aperture, and by the wet process.

I have once or twice tried dry processes, but with indifferent success. I am now seeing what the emulsion system will do in my hands, and, so far, I think I shall succeed. The greatest difficulty we have to contend with in tropical climates is the dampness of the atmosphere. In rainy weather—that is, during the wet season—the plates soon spoil. I am following the instructions given by "Photo-Chemicus," at page 130 of your YEAR-BOOK 1877, with the exception that, not finding the gelatine solution adhere to the glass, but run into patches, I apply albumen, white of one egg, 20 ounces water, 1 ounce strong ammonia as given by Jabez and Alfred Hughes, p. 49 of the YEAR-BOOK. The egg is shaken in a bottle (as recommended by Mr. Hughes in his work on Photography) with pieces of broken glass—I think a plan quite as efficient as, and much less trouble than beating with a whisk.

I notice different writers referring to the apertures with which they take views describe them by numbers. Now as I have not met with any description of these numbers as to the fractional parts of an inch they represent, I shall feel obliged if you will give me the corresponding sizes. In Mr. Rouch's Catalogue, 1877, p. 95, he has this: "with an aperture of $\frac{1}{36}$." Please what does that represent? As I expect the plates mentioned on that page are the emulsion plates above referred to, I am anxious to know the exposure required under the different apertures. I tried one with the $\frac{1}{36}$ aperture this morning, and exposed for half an hour, but with an indifferent result; however, I can account for that, as I tried to dissolve the nitrate in absolute alcohol when making the emulsion, and found it did not quite succeed; I ought to have used methylated.

"Photo-Chemicus" in his formula for the developer has omitted to say his pyro solution should be in alcohol. (See Mr. Rouch's formula, page 95 of the catalogue).

The likeness sent is printed upon Hone and Thorne-thwaite's albumenized paper that I have had by me for the last ten or twelve years. It is in a long tin case, and seems to keep remarkably well.—Yours very truly,

J. F. GRESHAM.

[The examples our correspondent sends are exceedingly creditable work when the difficulties are taken into account. He will find that the least troublesome plan is to adjust the ground glass so that it coincides with the position of the sensitive plate. The salted paper prints were a very good tone. The practice of numbering stops is adopted by

opticians, and the numbers have reference simply to the graduated apertures of each particular set, and have no relation to any recognized standard of size. It would be more convenient if a certain number really indicated a certain measurement. The aperture marked thus $\frac{f}{10}$ means that the aperture is one-tenth of the focus. The case to which he refers $\frac{f}{15}$ means that with a lens of fifteen inches focus, the aperture is half an inch. In making emulsions either methylated or pure spirit may be used; but it must contain a trace of water to secure solution of the silver salt. The YEAR-BOOK for 1876 is in print, and has been forwarded.—ED.]

A SIMPLE CARBON PRINTING WITHOUT PRINTING FRAME, ETC.

SIR,—The following may interest your readers:—Take carbon tissue from biobromate bath directly to the varnished negative, which is covered with wax and collodion, when dried, expose, and wash with warm water as usual. The autotype tissue will stick to the varnished negative more tenaciously than when after exposed. The carbon tissue can be made according to M. Fargier's, or Mr. Blair's, or Mr. Swan's process. The patent of the latter will expire next February, and other Woodburytype can be made with the above process easily. CARELESS OPERATOR.

Proceedings of Societies.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this Association was held on Thursday evening, the 2nd ult., at the Free Library, William Brown Street,—the REV. H. J. PALMER, President, in the chair.

THE SECRETARY read several letters, and showed some photographs that had been sent in from which to select a presentation print, but the Council considered it advisable to wait, in order, if possible, to obtain a suitable negative from those belonging to members.

Mr. Edward Le Robert's and Mr. Edward S. Seddon were elected members of the Association.

Mr. J. H. T. ELLERBECK read a paper on "The Use of the Actinometer with Dry Plates" (see page 478). He (Mr. Ellerbeck) showed some specimens of simple actinometers, which could easily be made and carried in the waistcoat pocket.

Mr. W. H. WILSON, in moving a vote of thanks to Mr. Ellerbeck for his paper, stated that the use of an actinometer is an undoubted advantage. He (Mr. Wilson) had on a former trip to the Continent found the light there so deceptive that he ought to have given exposures three times longer than he had done. On his last trip he took with him a slip of Durand's sensitized paper, and by noting the time it took to change to a certain tint he found he was able to judge the time of the exposure of his plates accurately, and had not under-exposed a single picture.

Mr. W. H. KIRKBY said he had been trying different samples of sensitized papers, and showed prints from the same. He had tried the borax bath, but in using the acetate bath, which he preferred, he had been recommended to add two grains of washing soda to the pint, and found it an improvement in toning Durand's paper.

THE PRESIDENT said that some of the plates he had coated for the members at their last meeting had been failures in their hands, while those of the same batch worked well with him. One, which he would pass round—an interior of the Walker Art Gallery—he thought was one of the best he had ever taken. He (the President) had tried an experiment, and found that he could coat twice as many plates with gelatine emulsion as he could with the same quantity of collodio-bromide emulsion.

A number of prints were exhibited by Messrs. Ellerbeck, Kirkby, Roper, Potter, and others.

Some charming prints were shown by the Secretary. They had been taken by Mr. Ellerslie Wallace, of Philadelphia, during a recent visit to this country, and attracted universal admiration.

After spending some time in examining a variety of things interesting to amateurs, which were exhibited by Mr. Ellerbeck, the meeting was adjourned until the 25th instant.

Talk in the Studio.

MR. SHERIFF NOTTAGE.—The *City Press* gives some interesting details of the history and antecedents of one of the gentlemen whose enterprise and ability are very familiar to the photographic world, and who, by his civic honours, confers distinction on photography. "Mr. Alderman and Sheriff Nottage is descended from the family of the Nottages, of Nottage, in Glamorganshire, who afterwards settled in Essex, in which county he spent his early youth. He is fifty-one years of age, and was married in 1851 to Christiana, daughter of Mr. James Warner, belonging to an old Cheshire family. His residence is at 35, Collingham Road, South Kensington, and his family consists of a son and daughter. He was for many years engaged in the large iron business of his uncle, Mr. B. W. Kennard, the late member for Newport. Mr. Nottage is a nephew of the late Mr. Alderman Challis, who for many years represented the borough of Finsbury in Parliament; and, strange to say, Mr. Kennard and Mr. Alderman Challis served the office of Sheriff of London and Middlesex during the same year. The Alderman was, a few years since, a candidate for a seat at the board of the Union Bank of London, which he lost only by a few votes, gaining, however, a moral victory by securing a majority of one hundred and nine of the proprietors over his opponent, Major Walker. Mr. Nottage having from his earliest years evinced a taste for the fine arts, and the stereoscope having then been invented, he saw that by this instrument in connection with the undeveloped art of photography, if brought out on commercial principles, a large and lucrative business might be established, and he at once threw his energies into the new enterprise, under the title of the London Stereoscopic Company, which has since developed into the largest concern of the kind, with agencies in various parts of the world. Sir David Brewster, the inventor of the stereoscope in its present popular form, at once interested himself in the development of his ingenious idea, and a prize being offered by Mr. Nottage for the best essay on the new optical instrument, he became the adjudicator, awarding it to Professor Louie. In 1862 the London Stereoscopic Company undertook the largest contract ever known in connection with photography, viz., that of the Great International Exhibition, purchasing from the Royal Commissioners, for a large sum, the exclusive rights of producing and selling photographs in the new building. The *chef d'œuvre* of modern sculpture, 'The Sleep of Sorrow and Dream of Joy,' by Monti, and Magni's celebrated 'Reading Girl,' there exhibited, being secured by him from those eminent sculptors. Mr. Nottage is not unknown in connection with literature, having some years since published, under the nom de plume of 'Persius Junior,' a series of amusing and trenchant sketches of character, and also having produced *The Shakespearean Diary*, under the initials of 'G. S. N.' Mr. Alderman Nottage is a member of the Spectaclemaker's Company."

ALDEGREYER'S ORNAMENTAL WORK.—"An album of photographic reproductions of Heinrich Aldegrever's ornamental work," says the *Academy*, "has just been published by the firm of H. Manz, at Munich. Aldegrever was a 'Little Master,' who, besides his small engravings of classical and other subjects, executed a large amount of ornamental designs for goldsmiths' work, book-decoration, and other purposes. A number of his plates of this kind are in the Royal Cabinet of Prints at Munich, and these have now been reproduced by J. B. Obernetter, whose skill in this kind of work we have before had occasion to commend. It is hoped that the Album will be found useful in schools of design, by giving a knowledge of a peculiarly German and fantastic mode of decoration."

PHOTOGRAPHERS' TOUTS.—*Figaro*, in giving some details of the history of a "fire eater" in a showman's caravan, gives some details of the antecedents of the photographer's "tout," who has generally been, it is stated, a "super" on the stage! "When this unlucky individual retired from his super's life, as I have said, he did not take to the fire-eating at once, but became the tout for a cheap photographer in the Euston Road. On questioning him further on this point, he informed me that these touts have almost, without exception, been on the stage. More than this, those who come from before the footlights to this occupation have, like Sterck, had tragic aspirations, and in many instances have actually been popular tragedians at the minor provincial theatres. The cause of their fall is usually,

in about eight parts of hot water at 160° (Fahr.), and a solution of about one part of bichromate of potash in about fifteen parts of water, or a solution of the before-mentioned bichromates or chromates in the same proportions. The mode of treatment in this case differs from the former only in two points:—1st. During the time the material is traversing through the bath, as already described, the solution is maintained at 160° Fahr. by means of siphon pipes charged with steam. 2nd. Instead of suspending to dry, the material is immediately passed over three steam cylinders seven feet in diameter, carrying a pressure of fifteen pounds to twenty pounds to the square inch. The cylinders are provided with gauges to indicate the pressure they are required to carry, and also with safety-valves to prevent this pressure from being exceeded. Although the bath is always in a state of darkness, yet it is specially necessary in this case, for without this the process of waterproofing the material by means of chromates or bichromates could by no possibility be accomplished.

"3rd. By treatment with acetate, sulphate, or chloride of alumina, applied in the form of a solution of about one part of any of these compounds in about six parts of water at 160° Fahr. The same conditions are required to produce a waterproof material with these compounds as those described above, with this difference, that it is not absolutely necessary to preserve darkness during the process. The claim of the patentee is thus worded:—

"Each of the foregoing processes I claim as my invention for the production of waterproof paper, cotton, or linen cloths, or other ligneous tissues. Paper and cloth may be taken together, through the treatment which, by its adhesive nature, binds the two together—thus giving a durable, pliable, and impermeable material suitable for any purpose where immunity from damp and moisture is required."

If the paper employed for silver prints could be made waterproof, it is probable that such an operation would tend towards permanency, and it is not improbable that a modification of some of the processes above described might be rendered available.

S. N.' Mr. Alderman Nottage is a member of the Spectaclemaker's Company."

ALDEGREYER'S ORNAMENTAL WORK.—"An album of photographic reproductions of Heinrich Aldegrever's ornamental work," says the *Academy*, "has just been published by the firm of H. Manz, at Munich. Aldegrever was a 'Little Master,' who, besides his small engravings of classical and other subjects, executed a large amount of ornamental designs for goldsmiths' work, book-decoration, and other purposes. A number of his plates of this kind are in the Royal Cabinet of Prints at Munich, and these have now been reproduced by J. B. Obernetter, whose skill in this kind of work we have before had occasion to commend. It is hoped that the Album will be found useful in schools of design, by giving a knowledge of a peculiarly German and fantastic mode of decoration."

PHOTOGRAPHERS' TOUTS.—*Figaro*, in giving some details of the history of a "fire eater" in a showman's caravan, gives some details of the antecedents of the photographer's "tout," who has generally been, it is stated, a "super" on the stage! "When this unlucky individual retired from his super's life, as I have said, he did not take to the fire-eating at once, but became the tout for a cheap photographer in the Easton Road. On questioning him further on this point, he informed me that these touts have almost, without exception, been on the stage. More than this, those who come from before the footlights to this occupation have, like Sterck, had tragic aspirations, and in many instances have actually been popular tragedians at the minor provincial theatres. The cause of their fall is usually,

in about eight parts of hot water at 160° (Fahr.), and a solution of about one part of bichromate of potash in about fifteen parts of water, or a solution of the before-mentioned bichromates or chromates in the same proportions. The mode of treatment in this case differs from the former only in two points:—1st. During the time the material is traversing through the bath, as already described, the solution is maintained at 160° Fahr. by means of siphon pipes charged with steam. 2nd. Instead of suspending to dry, the material is immediately passed over three steam cylinders seven feet in diameter, carrying a pressure of fifteen pounds to twenty pounds to the square inch. The cylinders are provided with gauges to indicate the pressure they are required to carry, and also with safety-valves to prevent this pressure from being exceeded. Although the bath is always in a state of darkness, yet it is specially necessary in this case, for without this the process of waterproofing the material by means of chromates or bichromates could by no possibility be accomplished.

"3rd. By treatment with acetate, sulphate, or chloride of alumina, applied in the form of a solution of about one part of any of these compounds in about six parts of water at 160° Fahr. The same conditions are required to produce a waterproof material with these compounds as those described above, with this difference, that it is not absolutely necessary to preserve darkness during the process. The claim of the patent is thus worded:—

"Each of the foregoing processes I claim as my invention for the production of waterproof paper, cotton, or linen cloths, or other ligneous tissues. Paper and cloth may be taken together, through the treatment which, by its adhesive nature, binds the two together—thus giving a durable, pliable, and impermeable material suitable for any purpose where immunity from damp and moisture is required."

If the paper employed for silver prints could be made waterproof, it is probable that such an operation would tend towards permanency, and it is not improbable that a modification of some of the processes above described might be rendered available.

LOCALIZING DEVELOPMENT IN CARBON PRINTING.

SIR,—By the following simple method I have succeeded perfectly in localizing and accelerating the development of carbon prints, and I now use it in daily practice. The method is as follows:—

I take a small piece of very soft wash-leather and wrap it round the finger; then dip it into a cup of warm water to which a few drops of ammonia have been added; then gently rub the portions of the carbon print that appear too dark and lacking in detail. For instance, it sometimes happens that the hair appears too dark and lacking in detail (especially in a Rembrandt picture), whilst the face and lighted portions are everything that could be desired.

Now, by adopting the method I have described, I find it possible to bring all the detail out in the darker portions and shadows, whilst the lighter parts are not in the least degree affected.

It is also a very rapid and easy method of reducing a rather over-exposed print, and by using the water hotter or colder, as the case may be, you have perfect control over the result. I find that it also cleans the surface of the tissue from all specks or dust that are liable to become attached to it from the washing-water or other causes, and which are very difficult to remove by an ordinary stream of water.

It is astonishing what an amount of friction the tissue will bear with the moistened wash-leather without in the least degree injuring the surface.

Should you think it worth while to give this a place in the columns of your valuable periodical, you are at liberty to make what use you like of it; if not, consign it to the waste-paper basket.—Yours obediently, THOS. B. LATONMORE.

AMATEUR PHOTOGRAPHY IN THE WEST INDIES.

DEAR SIR,—Do you think the following worthy a corner in your valuable publication? I have been dabbling in photography, off and on, for the last twelve or thirteen years. When I commenced I found great difficulty in obtaining a correct focus. I removed the lens, and with a rule measured the distance from the lens aperture to the focussing glass; I then put in a plate-holder with a glass and measured, but found the distances did not coincide. To remedy this I adopted the following plan, and have had no difficulty since:—I take a plate and gum over it the thickest and finest tissue paper I can get; when dry, I rub it with a little oil. This makes a capital focussing glass. When I wish to focus an object, I put this into the plate-holder and focus from it. When I afterwards insert the sensitized plate it necessarily occupies the precise place as the focussing glass. I enclose two views, one of Hope Vale Sugar Works, the other of part of the Carriacou with Government House in the distance; and I think you will admit a want of sharpness is not one of the many other defects. The views were taken some years ago, and have been recently printed upon plain salted paper. The exposure was about eight minutes, with $\frac{1}{4}$ inch aperture, and by the wet process.

I have once or twice tried dry processes, but with indifferent success. I am now seeing what the emulsion system will do in my hands, and, so far, I think I shall succeed. The greatest difficulty we have to contend with in tropical climates is the dampness of the atmosphere. In rainy weather—that is, during the wet season—the plates soon spoil. I am following the instructions given by "Photo-Chemicus," at page 130 of your Year Book 1877, with the exception that, not finding the gelatine solution adhere to the glass, but run into patches, I apply albumen, white of one egg, 20 ounces water, 1 ounce strong ammonia as given by Jones and Alfred Hughes, p. 49 of the Year-Book. The egg is shaken in a bottle (as recommended by Mr. Hughes in his work on Photography) with pieces of broken glass—I think a plan quite as efficient as, and much less trouble than beating with a whisk.

I notice different writers referring to the apertures with which they take views describe them by numbers. Now as I have not met with any description of these numbers as to the fractional parts of an inch they are; present, I shall feel obliged if you will give me the corresponding sizes. In Mr. Rouch's Catalogue, 1877, p. 95, he has this: "with an aperture of $\frac{1}{16}$ ". Please what does that represent? As I expect the plates mentioned on that page are the emulsion plates above referred to, I am anxious to know the exposure required under the different apertures. I tried one with the $\frac{1}{16}$ aperture this morning, and exposed for half an hour, but with an indifferent result; however, I can account for that, as I tried to dissolve the nitrate in absolute alcohol when making the emulsion, and found it did not quite succeed; I ought to have used methylated.

"Photo-Chemicus" in his formula for the developer has omitted to say his pyro solution should be in alcohol. (See Mr. Rouch's formula, page 95 of the catalogue).

The likeness sent is printed upon Horns and Thorne-thwaite's albumenized paper that I have had by me for the last ten or twelve years. It is in a long tin case, and seems to keep remarkably well.—Yours very truly,

J. F. GRESHAM.

[The examples our correspondent sends are exceedingly creditable work when the difficulties are taken into account. He will find that the least troublesome plan is to adjust the ground glass so that it coincides with the position of the sensitive plate. The salted paper prints were a great success. The practice of numbering stops is:

in about eight parts of hot water at 160° (Fahr.), and a solution of about one part of bichromate of potash in about fifteen parts of water, or a solution of the before-mentioned bichromates or chromates in the same proportions. The mode of treatment in this case differs from the former only in two points:—1st. During the time the material is traversing through the bath, as already described, the solution is maintained at 160° Fahr. by means of siphon pipes charged with steam. 2nd. Instead of suspending to dry, the material is immediately passed over three steam cylinders seven feet in diameter, carrying a pressure of fifteen pounds to twenty pounds to the square inch. The cylinders are provided with gauges to indicate the pressure they are required to carry, and also with safety-valves to prevent this pressure from being exceeded. Although the bath is always in a state of darkness, yet it is specially necessary in this case, for without this the process of waterproofing the material by means of chromates or bichromates could by no possibility be accomplished.

"3rd. By treatment with acetate, sulphate, or chloride of alumina, applied in the form of a solution of about one part of any of these compounds in about six parts of water at 160° Fahr. The same conditions are required to produce a waterproof material with these compounds as those described above, with this difference, that it is not absolutely necessary to preserve darkness during the process. The claim of the patentee is thus worded:—

"Each of the foregoing processes I claim as my invention for the production of waterproof paper, cotton, or linen cloths, or other ligneous tissues. Paper and cloth may be taken together, through the treatment which, by its adhesive nature, binds the two together—thus giving a durable, pliable, and impermeable material suitable for any purpose where immunity from damp and moisture is required."

If the paper employed for silver prints could be made waterproof, it is probable that such an operation would tend towards permanency, and it is not improbable that a modification of some of the processes above described might be rendered available.

Should you think it worth while to give this a place in the columns of your valuable periodical, you are at liberty to make what use you like of it; if not, consign it to the waste-paper basket.—Yours obediently, THOS. B. LATCHMORE.

AMATEUR PHOTOGRAPHY IN THE WEST INDIES.

DEAR SIR,—Do you think the following worthy a corner in your valuable publication? I have been dabbling in photography, off and on, for the last twelve or thirteen years. When I commenced I found great difficulty in obtaining a correct focus. I removed the lens, and with a rule measured the distance from the lens aperture to the focussing glass; I then put in a plate-holder with a glass and measured, but found the distances did not coincide. To remedy this I adopted the following plan, and have had no difficulty since:—I take a plate and gum over it the thinnest and finest tissue paper I can get; when dry, I rub it with a little oil. This makes a capital focussing glass. When I wish to focus an object, I put this into the plate-holder and focus from it. When I afterwards insert the sensitized plate it necessarily occupies the precise place as the focussing glass. I enclose two views, one of Hope Vale Sugar Works, the other of part of the Carriacou with Government House in the distance; and I think you will admit a want of sharpness is not one of the many other defects. The views were taken some years ago, and have been recently printed upon plain salted paper. The exposure was about eight minutes, with $\frac{1}{4}$ inch aperture, and by the wet process.

I have once or twice tried dry processes, but with indifferent success. I am now seeing what the emulsion system will do in my hands, and, so far, I think I shall succeed. The greatest difficulty we have to contend with in tropical climates is the dampness of the atmosphere. In rainy weather—that is, during the wet season—the plates soon spoil. I am following the instructions given by "Photo-Chemicus," at page 130 of your YEAR-BOOK 1877, with the exception that, not finding the gelatine solution adhere to the glass, but run into patches, I apply albumen, white of one egg, 20 ounces water, 1 ounce strong ammonia as given by Jabez and Alfred Hughes, p. 49 of the YEAR-BOOK. The egg is shaken in a bottle (as recommended by Mr. Hughes in his work on Photography) with pieces of broken glass—I think a plan quite as efficient as, and much less trouble than beating with a whisk.

I notice different writers referring to the apertures with which they take views describe them by numbers. Now as I have not met with any description of these numbers as to the fractional parts of an inch they represent, I shall feel obliged if you will give me the corresponding sizes. In Mr. Rouch's Catalogue, 1877, p. 95, he has this: "with an aperture of $\frac{1}{30}$ ". Please what does that represent? As I expect the plates mentioned on that page are the emulsion plates above referred to, I am anxious to know the exposure required under the different apertures. I tried one with the $\frac{1}{30}$ aperture this morning, and exposed for half an hour, but with an indifferent result; however, I can account for that, as I tried to dissolve the nitrate in absolute alcohol when making the emulsion, and found it did not quite succeed; I ought to have used methylated.

"Photo-Chemicus" in his formula for the developer has omitted to say his pyro solution should be in alcohol. (See Mr. Rouch's formula, page 95 of the catalogue).

The likeness sent is printed upon Hone and Thorne-thwaite's albumenized paper that I have had by me for the last ten or twelve years. It is in a long tin case, and seems to keep remarkably well.—Yours very truly,

J. F. GRESHAM.

[The examples our correspondent sends are exceedingly creditable work when the difficulties are taken into account. He will find that the least troublesome plan is to adjust the ground glass so that it coincides with the position of the sensitive plate. The salted paper prints were a very good tone. The practice of numbering stops is adopted by

opticians, and the numbers have reference simply to the graduated apertures of each particular set, and have no relation to any recognized standard of size. It would be more convenient if a certain number really indicated a certain measurement. The aperture marked thus $\frac{f}{10}$ means that the aperture is one-tenth of the focus. The case to which he refers $\frac{f}{15}$ means that with a lens of fifteen inches focus, the aperture is half an inch. In making emulsions either methylated or pure spirit may be used; but it must contain a trace of water to secure solution of the silver salt. The YEAR-BOOK for 1876 is in print, and has been forwarded.—ED.]

A SIMPLE CARBON PRINTING WITHOUT PRINTING FRAME, ETC.

SIR,—The following may interest your readers:—Take carbon tissue from biobromate bath directly to the varnished negative, which is covered with wax and collodion, when dried, expose, and wash with warm water as usual. The autotype tissue will stick to the varnished negative more tenaciously than when after exposed. The carbon tissue can be made according to M Fargier's, or Mr. Blair's, or Mr. Swan's process. The patent of the latter will expire next February, and other Woodburytype can be made with the above process easily. CARELESS OPERATOR.

Proceedings of Societies.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this Association was held on Thursday evening, the 27th ult., at the Free Library, William Brown Street,—the REV. H. J. PALMER, President, in the chair.

THE SECRETARY read several letters, and showed some photographs that had been sent in from which to select a presentation print, but the Council considered it advisable to wait, in order, if possible, to obtain a suitable negative from those belonging to members.

Mr. Edward Le Robert's and Mr. Edward S. Seddon were elected members of the Association.

Mr. J. H. T. ELLERBECK read a paper on "The Use of the Actinometer with Dry Plates" (see page 478). He (Mr. Ellerbeck) showed showed some specimens of simple actinometers, which could easily be made and carried in the waistcoat pocket.

Mr. W. H. WILSON, in moving a vote of thanks to Mr. Ellerbeck for his paper, stated that the use of an actinometer is an undoubted advantage. He (Mr. Wilson) had on a former trip to the Continent found the light there so deceptive that he ought to have given exposures three times longer than he had done. On his last trip he took with him a slip of Durand's sensitized paper, and by noting the time it took to change to a certain tint he found he was able to judge the time of the exposure of his plates accurately, and had not under-exposed a single picture.

Mr. W. H. KIRKBY said he had been trying different samples of sensitized papers, and showed prints from the same. He had tried the borax bath, but in using the acetate bath, which he preferred, he had been recommended to add two grains of washing soda to the pint, and found it an improvement in toning Durand's paper.

THE PRESIDENT said that some of the plates he had coated for the members at their last meeting had been failures in their hands, while those of the same batch worked well with him. One, which he would pass round—an interior of the Walker Art Gallery—he thought was one of the best he had ever taken. He (the President) had tried an experiment, and found that he could coat twice as many plates with gelatine emulsion as he could with the same quantity of collodio-bromide emulsion.

A number of prints were exhibited by Messrs. Ellerbeck, Kirkby, Roper, Potter, and others.

Some charming prints were shown by the Secretary. They had been taken by Mr. Ellerslie Wallace, of Philadelphia, during a recent visit to this country, and attracted universal admiration.

After spending some time in examining a variety of things interesting to amateurs, which were exhibited by Mr. Ellerbeck, the meeting was adjourned until the 25th instant.

Talk in the Studio.

MR. SHERIFF NOTTAGE—The *City Press* gives some interesting details of the history and antecedents of one of the gentlemen whose enterprize and ability are very familiar to the photographic world, and who, by his civic honours, confers distinction on photography. "Mr. Alderman and Sheriff Nottage is descended from the family of the Nottages, of Nottage, in Glamorganshire, who afterwards settled in Essex, in which county he spent his early youth. He is fifty-one years of age, and was married in 1851 to Christiana, daughter of Mr. James Warner, belonging to an old Cheshire family. His residence is at 35, Collingham Road, South Kensington, and his family consists of a son and daughter. He was for many years engaged in the large iron business of his uncle, Mr. R. W. Kennard, the late member for Newport. Mr. Nottage is a nephew of the late Mr. Alderman Challis, who for many years represented the borough of Finsbury in Parliament; and, strange to say, Mr. Kennard and Mr. Alderman Challis served the office of Sheriff of London and Middlesex during the same year. The Alderman was, a few years since, a candidate for a seat at the board of the Union Bank of London, which he lost only by a few votes, gaining, however, a moral victory by securing a majority of one hundred and nine of the proprietors over his opponent, Major Walker. Mr. Nottage having from his earliest years evinced a taste for the fine arts, and the stereoscope having then been invented, he saw that by this instrument in connection with the undeveloped art of photography, if brought out on commercial principles, a large and lucrative business might be established, and he at once threw his energies into the new enterprise, under the title of the London Stereoscopic Company, which has since developed into the largest concern of the kind, with agencies in various parts of the world. Sir David Brewster, the inventor of the stereoscope in its present popular form, at once interested himself in the development of his ingenious idea, and a prize being offered by Mr. Nottage for the best essay on the new optical instrument, he became the adjudicator, awarding it to Professor Louie. In 1862 the London Stereoscopic Company undertook the largest contract ever known in connection with photography, viz., that of the Great International Exhibition, purchasing from the Royal Commissioners, for a large sum, the exclusive rights of producing and selling photographs in the new building. The *chefs d'œuvre* of modern sculpture, 'The Sleep of Sorrow and Dream of Joy,' by Monti, and Magni's celebrated 'Reading Girl,' there exhibited, being secured by him from those eminent sculptors. Mr. Nottage is not unknown in connection with literature, having some years since published, under the *nom de plume* of 'Persius Junior,' a series of amusing and trenchant sketches of character, and also having produced *The Shakespearian Diary*, under the initials of 'G. S. N.' Mr. Alderman Nottage is a member of the Spectacle-maker's Company."

ALDEGREVER'S ORNAMENTAL WORK.—"An album of photographic reproductions of Heinrich Aldegrever's ornamental work," says the *Academy*, "has just been published by the firm of H. Manz, at Munich. Aldegrever was a 'Little Master,' who, besides his small engravings of classical and other subjects, executed a large amount of ornamental designs for goldsmiths' work, book-decoration, and other purposes. A number of his plates of this kind are in the Royal Cabinet of Prints at Munich, and these have now been reproduced by J. B. Obernetter, whose skill in this kind of work we have before had occasion to commend. It is hoped that the Album will be found useful in schools of design, by giving a knowledge of a peculiarly German and fantastic mode of decoration."

PHOTOGRAPHERS' TOUTS.—*Figaro*, in giving some details of the history of a "fire eater" in a showman's caravan, gives some details of the antecedents of the photographer's "tout," who has generally been, it is stated, a "super" on the stage! "When this unlucky individual retired from his super's life, as I have said, he did not take to the fire-eating at once, but became the tout for a cheap photographer in the Euston Road. On questioning him further on this point, he informed me that these touts have almost, without exception, been on the stage. More than this, those who come from before the footlights to this occupation have, like Sterck, had tragic aspirations, and in many instances have actually been popular tragedians at the minor provincial theatres. The cause of their fall is usually,

he further informed me, a 'goneness' at the knee, and a break down of the voice, which degenerates into what is popularly known as the 'gin whisper,' after a long course of tragical ranting, and frequent libations of the juice of the juniper berry, the favourite drink of the heavy tragedian, I understand. Sterck assured me that of the thirteen touts he knew between King's Cross and Portland Road station, no less than eight had been tragedians, two had been dramatic authors, one a Plymouth Brethren Evangelist, whilst of the other two he had been unable to discover their antecedents, though he thought they had been 'Turkish bath attendants,' till they became too limp to be of future use. Sterck did not long remain in the cheap photographer's employ. He was put in a semi-military uniform, and told to wink at the 'gale' on Sundays, two things that sorely troubled his gloomy soul. In fact he altogether mistook his calling when he became a tout of this sort, for, as his master plainly told him, his face was enough to frighten away all the would-be customers, who would imagine he (Tom Sterck) wished them to walk in to have their funeral cards printed in advance, rather than to have likenesses executed in first-class style, frame and glass included, for 1s."

OBTAINING MONEY UNDER FALSE PRETENCES.—At Bow Street, Charles Orsich, described as a photographer, of 352, Strand, was summoned before Mr Vaughan for obtaining money by false pretences. The defendant did not appear. Mr. Abrams, who appeared for the prosecution, said that for a long time past the defendant had been carrying on a system of fraud by advertising in different newspapers, mostly in the *Daily Chronicle* and *Daily Telegraph*, for young women to learn the business and assist in the photographic department. In order to entice people, and to give the business an air of probability, he had outside his shop a number of photographs of well-known persons—among them that of Mr. Beard, the solicitor, in his dress as Under-Sheriff of the City of London—entirely without those person's consent. In reality no business was carried on there, and the defendant and his wife lived entirely on what-ever premiums they could obtain from their victims. There were at present in court more than twenty young ladies who had been victimized, and who had paid premiums, amounting altogether to some £160, within the last six months, for situations with the defendant, where they could learn the photographic business. There was every reason to suppose the defendant had absconded, but the wife was still there, and declined to give up the clothes of two of the young ladies whom her husband had swindled. Mr. Vaughan directed an officer to go down and get the clothes for the young women, and ordered a warrant to be issued on a sworn information drawn up by Mr. Abrams for the apprehension of the defendant. George Wetton, one of the summoning officers of the Court, went down to the house in the Strand where the defendant occupied rooms on the second floor, and obtained the clothes of the young women.—*Times*.

INFLUENCE OF LIGHT ON THE ELECTRIC CONDITION OF METALS IN SALINE SOLUTIONS.—Metal plates were placed by Herr Hankel, one in a porous battery cup (closed by a cork) the other in a transparent exterior vessel. The vessels were filled with solution and enclosed in a blackened box in which was an aperture which could be closed at will, or before which coloured screens could be placed. With two plates of polished copper, plunged in water, the plate on which the sunlight fell was negative. The action of coloured rays reached its maximum in the blue. When the copper became more or less strongly oxidized or covered with salts, the plate, at first positive, then became negative, and kept its sign when the light was altogether suppressed. The action is ascribed principally to the feebly refrangible rays, while the dark blue or violet rays render the plate negative. Polished copper in sulphate of copper became first negative, and then strongly positive. Other metals gave the following results:—Clean plate of polished silver, in water, negative; lightly silvered platinum, positive; silver, covered with platinum, strongly positive; tin, negative; brass acted like oxidized copper. Amalgamated zinc, in solution of ZnO_2So_4 , strongly negative; ordinary zinc, nearly neutral (hence the action of the battery is due to the oxidized copper); and platinum, weakly positive. The author has also studied the action of heat on the zinc-copper-water element, of which he states the electric motive force becomes augmented, while it is enfeebled by light.—*Scientific American*

To Correspondents.

M. C. BRY.—We presume that a photographic chemist, if he did not keep it, would procure it for you. We have not occasion to purchase, and do not know certainly who keeps it. 2. We are not sure that any dry plates are specially suited for portraiture. The best portraits we have seen produced by the aid of dry plates were from coffee plates by Mr. Whitehead.

R. GORDON.—The addition of just sufficient ether for the purpose is the simplest mode of restoring the proper limpidity, and getting rid of the lumpy, irregular film.

H. W. M.—We do not make any charge to our correspondents for information or advice, but have pleasure in giving them the best information we can in this column quite freely. Write as often as you need advice or information. Pyrogallic acid is the best developer for opal pictures, and it is quite possible to get a warm tone; but that depends on many conditions. The bath must be in good condition, and moderately new. The collodion should be ripe. Then give a full exposure and rapid development. Make it a rule only to work in a good light, as you cannot get good results in this line without good light. Use three grains of pyrogallic acid, two grains of citric acid, and twenty minims of acetic acid to an ounce of water. Remember that a full exposure and rapid development will tend to warmth of tone, if you have to push the development you produce black tones by prolonged development. Bear in mind that the same conditions which would produce a weak, thin, grey, negative will produce a poor thin image on opal.

S. B.—We regret that we cannot in this column give you detailed instructions, as they would require too much of the space devoted to answering correspondents. You will find full instructions on p. 40 of our Year-Book for 1870. But you will bear in mind that any method of photographing direct on painter's canvas is a somewhat dangerous method to adopt for the basis of an oil painting, as it is very difficult to remove the hyp, used for fixing, as canvas cannot be washed as a print on paper can. The plans considered best in the present day are transfer processes, either a collodion print or a carbon print transferred to canvas making a much more trustworthy basis for a painting in oil.

H. SYMONDS.—Your letter arrived too late for answer in last News; but, as you would see, the information as to the date of sending in was furnished in Mr. Pritchard's note of reminder. The Exhibition opens next Tuesday evening.

TRANSFER, R. B.—The Autotype Manual gives full instructions for transferring carbon prints to canvas. We have never tested the method there described, but we have years ago used a somewhat similar method. We first washed the face of the canvas with soap and warm water, using a piece of flannel to thoroughly remove grease, &c., finally rinsing with alcohol. We then treated its surface with a very weak solution of gelatine to which a little spirit was added. We then applied the developed print to the surface of the canvas, which was, of course, moistened, and pressed the two well together. On lifting the canvas afterwards, when all was dry, it brought the print with it.

A. BELGIAN SCHREIBER.—We have never found a bath of pure india-rubber contaminates the silver bath or causes it to discolour, and we should be disposed to believe the result you describe to be caused by some adulteration or impurity in the india-rubber. Probably varnishing with shellac will prove a remedy.

ENR.—We have no means of knowing any method of securing an engagement as a photographer in Gibraltar. There is nothing, we fear, but trying the experiment.

JAMES HARVEY.—There is no difficulty in producing transparencies by the wet process without a camera, but such transparencies are not perfect enough for enlarging purposes, as they are not quite sharp. A strip of stout writing paper or thin cardboard is laid each time at each end of the negative, and the wet plate placed in contact. The loss of definition is not serious, but too serious to be amplified in enlargements. It is possible to place the sensitive plate in direct contact with a varnished negative, but it requires much care, and involves some risk. 2. "Harmonious Colouring Applied to Photographs," published by Newman, Soho Square, will answer your purpose.

G. W. G.—It is not customary to make any acknowledgment of photographs sent for registration except in the News at convenient intervals. The expense of the operation would be increased if it involved much correspondence.

T. H. CHURCH.—There is no fault in the toning of the print you enclose; it simply required a good deal of over printing. 2. The spots on the piece of paper enclosed arise from the paper having been in contact with some injurious substance before placing in the silver bath. Hypsulphite appears to have been the substance. Never change the dishes from one use to another. Have suff sent for each purpose, and keep each to its purpose. 3. We cannot recommend any special paper. The dry process you name is one of the best and simplest. The mode of development was given in a subsequent number. You will find it all detailed in the last Year-Book of Photography. The plates must be changed in the dark.

The Photographic News, October 12, 1877.

PHOTOGRAPHY IN AND OUT OF THE STUDIO. A READY MEANS OF SECURING NEGATIVES FROM MAPS OR PAPER PRINTS.—PHOTOGRAPHS FROM THE SEAT OF WAR.

A Ready Means of Securing Negatives from Maps or Paper Prints.—We have spoken on several occasions in these columns upon the application of the flexible film of Mr. Warnerke to the reproduction of clichés and negatives, but one of the most important uses to which we have seen the emulsion tissue put is that of copying maps and paper photographs. For military purposes the method will be invaluable, for the Warnerke tissue offers not only a rapid means of disseminating the work, but of preserving the finest details of the original. An ordnance map, the fine shading and dotted lines of which cannot but suffer when reproduced by means of the camera, are preserved intact by contact printing in a pressure frame with the Warnerke film, for neither one nor other of the surfaces being rigid, the two can be pressed into immediate contact. At the same time, a whole mass of operations fall away at one time, and only those who know what it is to reproduce plans and maps, whether for photo's, lithographic or simple photographic printing, can thoroughly appreciate what this means. The setting up of the original at a perfect right angle to the lens, the fixing of a central point, and the focussing of the lens so that the lines shall be as sharply defined as possible, are all of them laborious and time-taking operations. In lieu of them the map or plan is simply placed in contact with the tissue, the two prepared surfaces together (that is, the printed face of the map and the sensitive surface of the tissue), and the light is then permitted to act through the paper of the map upon the film. Curiously enough, there is in the result no trace of any texture from the paper, whether it is because the comparatively long exposure given in printing (a few minutes) diffuses the action of the light, or that, no gloss being employed at the back of the film, there is no chance of any reflection or refraction taking place. Even delicate photographic prints we have seen dismounted from cardboard, and placed in this way in contact with the tissue, the result being a capital negative that yields impressions hardly to be distinguished from the original. In fact, any photographer who possesses so much as a *carte-de-visite* may in this way put himself in possession of a dozen negatives from the same in a few hours. In one or two instances, we must admit, we have been unable altogether to get rid of a slight trace of texture where the photograph has been printed upon very thickly albumenized paper, but even in these cases the defect was only visible to an experienced eye. The great thing is to give thorough exposure, for the Warnerketissue, if it is always convenient, is apt, at times, to be a little insensitive. But employed in this way, printing in a good light for three or four minutes means, of course, a very long exposure, and you will find that with such a printing the tissue bears a very visible image, which on development comes out with singular detail. Although it is generally supposed that in developing emulsion films very much over-exposed a necessity exists for reducing the strength of the alkaline solutions, we must frankly say that we have never found this to be really called for. In other words, the solution which Mr. Warnerke recommends for the ordinary development of his tissue, after exposure in the camera, we find not too strong for the development of a sensitive surface which has been exposed behind a map on plate paper, or an ordinary albumenized print, for three or four minutes. The image comes up quickly, it is true, but every detail arises prominently and at once, so that there is no reason to press the development and run the risk of fogging. The tissue thus places in the hands of photographers a particularly easy and ready way of turning a paper print into a negative, or a dozen of them if necessary. They need simply to keep a few inches of the tissue by them, and at any moment are

in a position to secure a printing negative, so long as they have a print in their possession. But it is, as we have pointed out, a means which will prove essentially valuable for multiplying maps and sketches for military purposes. Where the question of reduction enters into the matter, we must, of course, still make use of the camera, but to reproduce a map as accurately as possible, with all its details, the tissue will come in very handy. A lens may not distort much, but still it cannot be perfect in its rendering, and in the case of a war map even the least distortion may at times be of importance, and for this reason reproduction direct by the film will be preferred to the other and older method. In the case of the last Franco-German war, we are told that when Gambetta came out of Paris in a balloon, and most of the French regular troops were shut in the capital or at Metz, the greatest difficulty he found with his new army was to supply it with information respecting the roads and bye-ways of the country. There were maps in plenty, and plates from which a further supply could be struck, but these were all locked up inside Paris. Fortunately, the widow of a general officer living at Tours had some copies of the ordnance maps, and from these Gambetta managed to secure copies by means of photo-lithography. But had, at the time, the emulsion film of which we are speaking been available, not only would it have been possible to secure copies more rapidly, but these, being printed by transmitted light from the original map, would have contained every detail without loss of a single point.

Photographs from the Seat of War.—We are glad to see that photographers are not altogether so apathetic on the subject of the war as we supposed. It seems that a Bucharest photographer has at last summoned courage to take a camera into Bulgaria, and was last heard of at the Russian head-quarters at Gorny Studen. It would not seem a very serious undertaking, after all, to take photographic apparatus into the field when provided with a Russian permit, for some of the views M. Duschek has taken tell of anything but hard campaigning. Indeed, the camp scenes we are shown suggest the reason of the Russian non-success. We see everywhere the space crowded with empty vehicles, not military waggons and ambulances, but of a nature used for transporting officers' luggage, and what might fairly be termed luxuries. According to many of the special correspondents, the superior officers drive from one part of the scene of operations to another, so that, so far as they are concerned, it is a campaign on wheels. This is borne out by M. Duschek's photographs, where carriages and horses are to be seen in large numbers, and especially in the vicinity of the headquarters. Bulgaria may not furnish very many delicacies, but whatever can be obtained appears to be forwarded to the Czar at his headquarters, where, we are told, waggons arrive daily from the Danube loaded with luxuries and good things for the Imperial. As a companion picture, we ought to have a photograph of the present Turkish Commander-in-Chief's headquarters, Suleiman Pascha, who sleeps, we are told, in a tent so small and low that he is obliged to creep into it on all fours. In lieu of purple flags and stately tents to mark the residence of his staff, this also finds accommodation under shelter of the same humble description. It would be well if we could have photographs of the two headquarters side by side; they would teach us a good deal, probably, of the character of the men now in chief command of the opposing armies.

POTASSIUM AND SILVER PERMANGANATES; THEIR PREPARATION AND PHOTOGRAPHIC UTILITY.

BY WM. HOWARD.

OCCUPYING a prominent position amongst the re-agents which have been pressed into the service of photography,

stands permanganate of potassium. This salt, which is the only one of its series manufactured largely, may be used as the source from which to derive its lesser known brethren, including the silver permanganate. The potassium permanganate can also be made to yield up its permanganic acid in the free state.

Although, having regard to the facility and cheapness with which this salt may be obtained in a pure state, it is neither desirable nor necessary to attempt its preparation when required for use in the laboratory or dark room, still a short *resumé* of the methods by which it can be produced may be of service to those who are but imperfectly acquainted with its chemical composition. The most simple statement of its component parts is this: the salt consists of potassium, manganese, and oxygen. A very small knowledge of the nomenclature of chemical compounds enables us to comprehend that there are compounds of these three elements which contain less oxygen than the permanganate. It is from one of these, not by any process of direct combination, that the latter salt is produced.

For instance, whenever potassium carbonate and black oxide of manganese (di-oxide) are strongly heated together, with free access of air; or, better, when with caustic potash, manganese di-oxide, and potassium chlorate—an oxygen giver—are so treated, the result is a greenish semi-fused mass, which contains *manganate of potassium*; and, in the last case, chloride of potassium also. This mass treated with a small quantity of cold water forms a deep green solution of the alkaline manganate which may be obtained in crystals of the same colour by evaporation over sulphuric acid in a vacuum. The symbol for the manganate is:— K_2MnO_4 ; that is to say, two equivalents of potassium are united to one of manganese and four of oxygen. The *permanganate* is written $KMnO_4$, one atom of potassium only entering into combination, the proportion of oxygen being therefore much greater than that existing in the manganate. If the green solution obtained as above described is heated, or even freely diluted with cold water, decomposition of the manganate at once takes place, and the result is the formation of potassium permanganate together with manganite of potassium, which immediately gives up its potash to the water, forming caustic potash, and depositing pure hydrated peroxide of manganese, thus:—

By evaporation, the permanganate is crystallised out on cooling, but is too well known to require description here. The most characteristic property of the permanganates is that they readily part with a large proportion of their oxygen to organic or other bodies having affinity for that element. It is to this readiness to effect at once the complete oxidation of decaying and offensive organic matter that the permanganates owe their power as disinfectants (Condy's fluid), and to this power is due also their usefulness in photographic operations.

The chief uses to which permanganate is usually applied by the photographer are:—1st. The intensification of carbon transparencies, or either carbon or silver negatives. 2nd. As an agent by means of which to remove organic impurities from the negative bath.

The employment of permanganate of potash as an intensifier, though not so important an application as the other, I have given precedence to, because it is more generally practised, and depends upon the oxidising power of that salt for its efficiency. Strictly speaking, it is not true that intensity is gained because the permanganate imparts oxygen to the material of the carbon picture, or to the film of the silver negative. This gain in intensity depends rather upon the fact that whenever permanganic acid, either free or combined with a base, parts with oxygen,

manganese dioxide is thrown down, a new acid being formed from the oxidised body. In the ordinary process of intensification with permanganate of potash, the manganese dioxide is deposited in the body of the transparency or negative, thus adding to its opacity; the new acid formed by the oxidation of the organic matter present, combining with the potash, forms a soluble salt.

The use of permanganate of potash for the removal of organic matter from the silver bath—printing or negative—which is *directly dependent* on the modification of that impurity through the acquisition of oxygen, deserves a more minute notice. Permit me on this subject to quote the words of a recent article in *Photographische Notizen*:—"The only trustworthy means of decomposing the organic substances in a bath—namely, by the use of permanganate of potash—is not yet sufficiently valued by photographers. And the reason for this is to be found in the circumstance that few operators understand how to employ the same properly." To the first of these propositions I can most cordially assent. The reason assigned is, I think, scarcely correct. The method of using permanganates for bath purification has been more than once described in our journals. The writer of the article quoted above, of which a translation appeared in this paper, very carefully particularizes the appearances which should guide the operator, but entirely omits the details of the changes which then take place. Herein, I believe, is discoverable the reason to which must be assigned the insufficient value often attached to permanganate as a bath renovator. The photographer of to-day, more educated than he of former years, demands that every reagent prepared for a specific purpose shall be furnished with proper credentials by which he may judge of its actual value, before he ventures upon its use.

I have recapitulated the general nature of the reaction between permanganic acid and an organic body; it remains now to exhibit clearly what secondary actions take place when a silver bath is subjected to such treatment.

As being the first object of a photographer's solicitude, the negative bath forms an apt subject from which to draw the requisite illustrations. The main organic impurities of a negative bath which has been in use are alcohol and ether. Boiling is both troublesome and expensive, and does not entirely expel the enemies; sunning requires a long exposure to the necessary influence, and is, like boiling, not altogether effectual. The effect produced by sunning, or more rapidly induced by boiling, a silver solution containing organic matter is, in its ultimate result, the exact parallel of that which immediately occurs upon the addition of a permanganate. The means by which the same end is attained are, however, very distinctly traceable to opposite sources. When a bath is boiled or sunned, the alcohol and ether which contaminate it are oxidised at the expense of the nitrate of silver contained therein. As I have in a preceding contribution remarked, this reaction is a very convenient one to take advantage of when it is desirable simply to destroy the comparatively small amount of organic matter present in ordinary water; but when the negative bath, or other working solution, requires to be freed from such impurities, it is not quite so satisfactory in its operations. Unless a very impracticably long exposure to light is permitted, the ultimate stage of oxidation—in the case of the negative bath the conversion of the alcohol and ether in acetic acid, and the consequent conversion of the silver oxide which at first forms into acetate of silver—is never reached; neither does boiling effect this complete conversion. Practically speaking, both sunning and boiling simply partially destroy the organic matter in silver solutions, giving a deposit of silver oxide, which is subsequently removed by filtration, and weakens the solution operated on in a degree exactly proportioned to its quantity. Permanganates, on the other hand, at once completely oxidise the alcoholic enemies into acetic acid, producing an equivalent quantity of the acetate of the base contained in the permanganate used, and as they

supply the oxygen necessary to bring about the transformation, no reduction or removal of nitrate of silver can occur. These two points—the completeness of the oxidation, and the non-abstraction of silver salt—are grounds sufficient upon which to advocate the employment of permanganates.

(To be continued.)

SPOTS ON EMULSION PLATES: THEIR CAUSE AND CURE.

BY W. BROOKS.*

Now that the emulsion process fairly ranks, with the landscape photographer, as one of the foremost processes of the day, I venture to bring it again before your notice. Some years since I said at one of the meetings of this Society that I thought the emulsion would take the place of the nitrate of silver bath. At the time this was doubted, but I have not had any reason to alter any opinion on the matter; for, during the past season, I have only used the bath once, and that was because I had not any emulsion then ready. Formerly I contented myself by working with a slow emulsion which was very certain. I am now using a very rapid one of my own make, and I can say, without the slightest hesitation, that it is more rapid than the ordinary bath plate, everything being in good, fair, working order, so that I am now quite independent of the bath, and see no reason why I should take to it again, especially for field work.

About the middle of the present year I had a large quantity of work on hand, and when I had to prepare the plates in large numbers I was troubled with spots. I had previously been quite free from them. Several had asked me if I had any spots, and my reply was always "no," until the time before stated. I was told that I was a lucky fellow. But my luck failed me at last, and then I set about to find the cause and the remedy, which I did, but not without a great deal of trouble and anxiety; and now that I am quite free from them I beg to offer the results of my investigations for the benefit of those so troubled.

In the last three issues of the *British Journal*, in articles by the Editors, there are several good suggestions as to the cause of a certain class of spot. In my experience I find three kinds of spots. No. 1 is a transparent spot, with a small black speck in the centre; this kind of spot altogether is not more than about one-eighth of an inch in diameter. No. 2 is a transparent spot also, but without a nucleus (or black spot in the centre), and has a ring of wave-like markings; this kind of spot is sometimes as much as half-an-inch in diameter or more—a regular patch. No. 3 is quite the opposite to the foregoing, being quite opaque throughout, the largest seldom being more than an eighth of an inch in diameter; this kind of spot is more uncommon than the two former.

I will deal with spot No. 1 first. I think there is not a question as to the cause of this kind of spot, and that is dust settling on the plate during the evaporation of the solvents ether and alcohol; and it is the kind of matter constituting this particle of dust that determines whether the resulting spot be transparent or opaque. Should that particle of dust be some inert substance, the result is only a pinhole; but should it be a retarding agent, such as a small particle of a bromide, iodide, or an acid substance, the essential part would be readily dissolved by both the ether and the alcohol, causing the parts round the substance so deposited to become insensitive to light, and originating the transparent spot, with the substance, whatever it may be, forming the nucleus. When the plate is nearly dry, before the dust falls on it, the resulting spot will be small, and perhaps not perfectly transparent throughout; but should any dust fall upon the plate when dry, no matter of what it is composed, it does not appear

to injure the plate in the slightest degree. When preparing only a few plates (about a dozen) I used a cupboard; but when I had to prepare larger quantities at a time I used a large box as well, and the plates set to dry in this large box were the ones that had the class of spot I designate No. 1, and they only occurred when I closed the lid. If I allowed the plates to dry without closing the lid they were free from that class of spot; hence I have no doubt they were caused by dust on the inside of the lid of the box becoming detached and falling on the surface of the plates in the moist condition on closing, the plates being in the box film outwards; and I think in nine cases out of ten many would use a box (and close the lid) for the purpose. I cannot agree with the writer of one of the articles in *The British Journal*, where he says that by dust falling into the emulsion, when poured out on the plate, it then, and only then, affects the film. My opinion is that anything falling into the emulsion—supposing it to be a restrainer or retarding agent—by virtue of the alcohol or ether the active principle would become dissolved, and be diffused throughout the whole of the compound, and would tend only to make it slower. On the other hand, supposing it to be a reducing agent, the small particles would be almost sure to be dissolved, and would do but very little harm (if any), and any substance that might be left behind would be of a sandy nature. To test this I have put all sorts of rubbish into the emulsion, and, after shaking it and letting it settle, have prepared plates that worked as well as ever.

I now come to the class of spot I call No. 2. This has a totally different origin altogether from the preceding one, and will also occur in the closed box before mentioned, especially if the solvents used be of a weak nature. I have seen the question frequently asked—"Why do spots occur in washed emulsion plates, and not with those prepared with an emulsion that has not been washed and dried and redissolved?" On a little consideration it is easily understood. The first named, known as washed emulsion, is poured over the plate and allowed to dry; that is, to allow the ether and alcohol to evaporate. Not so with the other kind. After the film has been washed and passed through the preservative and set to dry, only water has to evaporate. This kind of plate is generally free from spots; but, when using the washed emulsion, and the spirits have to evaporate, matters are changed. It is a well-known fact that strong alcohol has a great affinity for water, and, if the atmosphere be damp, water is attracted from it, causing the plates to dry patchy; and there is not only the affinity of alcohol for moisture to be contended with, but also the chloride of silver contained in the emulsion, as all chlorides absorb moisture. It will also be remembered that, in the days of the collodio-chloride emulsion, spots used to be troublesome. I know they were so with me, and that may be the cause why a chloride cannot be successfully worked in a gelatine emulsion. When the collodio-emulsion plates are dried in a damp or humid atmosphere they attract the water in patches; for, if plates are watched, the last parts that become dry are circular spots. These remain damp a long time, and that part of a plate that is a long time in drying seems to be the most insensitive. I had, to my regret, a batch of plates spoiled from having been prepared in a damp atmosphere in a butler's pantry just after it had been cleaned and washed up, and when there was no possible chance of dust. The last part of the spot to dry was, of course, the centre, and when the plates were developed the centre was the most transparent part. Some of these spots were quite half an inch in diameter. Of course, in this case, there was no nucleus.

The spot No. 3—the most uncommon—I suppose to be perhaps the dust of nitrate of silver or some alkaline agent. On the application of a dust of silver it makes its appearance as a black, opaque spot as soon as the ammonia is added to the developer; but, should it be an alkaline

* Read before the South London Photographic Society.

agent, a black spot appears as soon as the pyrogallie solution touches it, and that part of the film at once becomes reduced.

Having stated the cause of the 'spots' of the different classes as they have occurred in my practice, I will now point out the remedy. It is best to use neither boxes, drying-boxes, nor cupboards, and avoid damp atmospheres if possible. In my work I am now perfectly free from spots, and I proceed in this manner:—After the glass is cleaned I edge the plate, in the usual manner, with India-rubber, and a flat, stiff, hog's-hair brush is passed over the plate to remove any dust. I find the best kind of brush for this purpose is the flat hog's-hair varnish brush, such as is used to varnish oil paintings, very suitable. After I have coated two or three I dry them by means of a kind of hot-water bottle, which gives a very steady heat. If too hot when the water is first put in a thickness or two of cardboard is put over it, which is removed as the temperature gets lower. By keeping the spirits evaporating moderately rapid there is no chance of spots of the kind of No. 2; after being once dry they are perfectly safe. Keep away the dust, and spots Nos. 1 and 3 are out of the question. If the plates are made to dry by means of a current of air, that current of air will be sure to carry with it dust, and spoil the plate. I quite agree with Mr. Woodbury when he says that plates are best dried by means of heat.

In conclusion: I may say that an emulsion properly made is not so liable to get out of order as the nitrate bath. I have put all sorts of things in emulsion, by way of experiment, that would quite ruin the bath, and it has not injured the emulsion in the slightest. At one time I thought spots had a different origin to what I do now. Many say that if the emulsion be not allowed sufficient time to settle, spots occur. To try the effect, I have prepared plates directly I have shaken it up, and dried them off by heat, without any of the kind of spots above named. The only description of spot that can then make its appearance is a kind of sandy one. I trust what I have said may be the means of putting the emulsion process on a better footing; for I think there is nothing more provoking than to have what would have been a good negative ruined by a collection of spots.

KRUGER'S ARGENTOMETER.*

Herr JULIUS KRUGER has just constructed a new argentometer, to which we desire to call the attention of our readers. All the argentometers hitherto in vogue had particularly two defects: either they were in the highest degree untrustworthy, or they were most elaborate to use, except in the hands of scientific photographers. The so-called *scalens-argometer* gives in the case of freshly-prepared silver baths results of extraordinary accuracy; but this is not the case with impure solutions, such as are produced with the print bath; in the latter case other salts in solution are recorded as silver salts.

So far as the Vogel argentometer is concerned, this is beyond measure trustworthy; but it is hardly an instrument which everyone can use, and cannot, moreover, be carried about everywhere.

Herr Krüger has avoided these two drawbacks, and invented an argentometer which can easily be used, does not take up much space, and yields the most accurate results. By the aid of this instrument the photographer may in a very short time determine the percentage of nitrate of silver in his baths, reading the amount off upon a scale.

The principle upon which the invention is based is the following. Everybody knows that a strip of pure copper dipped into a solution of nitrate of silver becomes at once covered with a deposit of metallic silver, while a portion of the copper goes off into solution, as may be perceived from

the circumstance of the solution turning blue. In this case, a substitution process goes on, an atom of copper taking the place of an atom of silver in solution; the process goes on until the solution of silver is exhausted, or until the copper is all dissolved. The operation is expressed in the following formula:—

Nitrate of silver = Nitrate of copper + silver + copper.

We find that 170 parts by weight of nitrate of silver go over to 31.7 parts of copper to form 93.7 parts of nitrate of copper, and 108 parts of silver; or, in other words: 31.7 parts of copper reduce 108 parts of metallic silver from 170 parts of the nitrate of that metal. From a given volume of silver bath all the silver may be thrown down in a metallic form, and from the loss of weight suffered by the copper (for the attached silver is easily removed) the percentage of silver in the bath may be easily calculated—the result being read off on a table constructed for the purpose. This is the principle upon which the Krüger argentometer rests.

The sketch given below will give some conception of the

instrument, which resembles, in fact, a decimal-balance. Upon a board is a stand upon which the balance stands. On the left is a strip of copper, while on the other side is a screw arrangement, which can be moved forwards or backwards to adjust the weight. It is easy to understand how the apparatus works.

If a photographer desires to find out the strength of his bath, he first of all adjusts the screw on the beam in such a way that the index rod points to 0; then a vessel belonging to the apparatus is filled with the liquid to be tested to the extent of ten cubic centimetres, and the measured quantity being afterwards poured into a beaker with some slightly acidified water, so that there may be plenty of liquid wherein to place the copper strip. This, after the balance has been accurately swung, is detached from the beam (the movable screw not being tampered with), and the copper placed in the beaker of diluted silver solution, the strip being from time to time moved about to quicken the precipitation of the silver.

The reduction of the nitrate of silver, or the substitution process, at once begins, and the copper strip proceeds to cover itself with a film of metallic silver, which, as we have already said, is easily removable. When the operation is deemed finished, the strip of copper is withdrawn, and the attached silver is removed with the aid of a piece of filter-paper, which should not, of course, be thrown away. If when the strip is again put into the beaker of solution the former remains unchanged, the reduction of the silver is complete; but if, on the contrary, the signs of reduction still go on, then the introduction of the copper strip must again take place, and so on till the solution is really exhausted. In the end there should be no change observable upon the surface of the copper, and this desideratum is soon attained.

When the copper is finally cleansed from the adhering silver, it is again hung upon the beam of the balance from which it was detached. It has become lighter since some of its mass has been dissolved, and the consequence is the index bar, instead of pointing to 0, goes off to the left, and the number on the scale at which it comes to rest indicates the percentage of silver in the solution which has been experimented with.

* Photographische Wochenblatt.

The objection that the free sulphuric acid in the silver bath would bring about a dissolution of the copper is as unfounded as the idea that the acetic acid which is added would bring about this result. In the first place, both acids are found in the silver bath in such a state of dilution that at an ordinary temperature, at any rate, they could have no material influence; and secondly, it must be borne in mind the copper remains in the solution but a very short time in any case. We have, we may mention, kept the copper strip for days in a fluid which consisted of two parts water, one part nitric acid, and one part acetic acid, and yet the finely constituted balance did not show any diminution of weight in the strip afterwards.

We hear that Herr Küger is patenting his instrument, and that it will speedily become an article of commerce.

RETICULATION AND BLISTERS.

BY D. T. BURRELL.*

THERE have been several articles written about reticulation in the carbon process, but I have seen none on blistering. I have reference to those about the size of a pin head and smaller.

As I have been troubled with both of the above for the past two weeks, and have fought my way through them successfully, I will give my experience for the benefit of others.

I studied up every article I could find on carbon, but none seemed to hit my case. One writer said that reticulation "can be produced or not produced absolutely at will;" but I soon found I could not rely on his statement, as they came about the same when the tissue was dried slowly as when quickly dried by artificial heat. I also tried different samples of collodion as well as different samples of tissue, and then without any collodion, and still they came, but not quite so much with thin as with thick collodion. I experimented with the sensitizing bath, and had been using a three per cent. solution with from twenty-five to thirty drops of ammonia. I substituted soda for ammonia with no better result. Determining to leave no stone unturned, I tried different temperatures of the sensitizing bath; also of the water before transferring as well as for developing. Drying slowly or quickly after developing the result was always the same—reticulation; and when a little over printed, a little extra developing would cause blisters. I inquired of those who had had many years' experience in carbon work, and they could not tell me how to get rid of them, but suggested that I should try a weaker sensitizing bath; by the way, I had reduced it one-half, but without the desired effect. I could not think it was too strong, for I had used the same for over seven months, making better work than I had ever done in silver, all my enlargements being made with it, both single and double transfer. I was beginning to feel discouraged (but no more than I had several times with the silver process). Now for one more trial with a weaker bath—one ounce of bichromate in ninety ounces of water; five drops of ammonia and three ounces of alcohol—and the result is that reticulation and blisters have all disappeared. Positives as well as transparencies are all that can be desired.

I have always been told that it would not do to use the sensitizing solution but once; that by using it over I could not get pure whites, &c. I have used the same solution for over two weeks, sensitizing every other day, and used over one band of tissue, floating about one and a half minutes and filtering each time. The prints came out all right; and to prove that they were all right, the last time I sensitized I made a new bath and tried a piece in the new and one in the old, and if I had not marked them I should not have been able to tell by the appearance of the prints

which was which. I have come to the conclusion that I have thrown away several pounds of bichromate by only using it once.

Instead of floating wax solutions on the developing plates, it saves much labour to use French chalk; also a rubber solution around the edges to hold the collodion, dries quicker than gum solution made with water, and holds better.

I have also found that dark or deep shadows can be removed with a tuft of cotton when the parts to be lightened are large, and the small spots or specks by the use of a soft pencil brush by stippling or drawing it lightly over the dark parts, while they are yet wet, with the warm developing water.

With soft or thin negatives[†] freshly sensitized tissue gives the best results; for intense negatives, or those with strong contrasts, the tissue should be sensitized three or four days. If there are any other workers in the carbon process who have met with the above difficulties, or any other trouble, I should be glad to hear from them, or exchange samples with them.

RETICULATION IN CARBON.

BY J. INGLIS.*

As reticulation seems to be the bane of carbon printing in hot weather, allow me to give you my cure, which has in my hands been perfect.

Instead of using the sensitizing solution of two and a half per cent., as stated, use only one and a half, and immerse until the tissue lies nice and flat, the temperature not being higher than 60°, and as much less as may be convenient. The quicker the drying, the better. If the weather is damp and a long time taken to dry the tissue, it will be very hard to develop, and the results will not be so clear and bold as if dried quickly. I find that I can keep it in first-class working order for four and five days in hot weather, and in cool weather over a week, easily. The water used before transferring the tissue must not be higher in temperature than 56°.

Before I used the cold water for transferring I was greatly troubled with the half-tones washing away and leaving hard print; since adopting the weak sensitizer and the cold water for transferring, I have not had the first signs of either of the above troubles. In developing on clean glass, it is very hard to judge when the prints are exactly light enough by looking through them against a white ground. A plan I have fallen on, which is much more certain, is to look through them against a shade or anything dark. I look for the high lights, and when they just begin to show clear glass (which is easily noticed by holding them opposite anything dark), I stop the development.

Another useful dodge is to use a solution of bicarbonate of soda in very hot water, to reduce an over-printed picture. I develop four cabinets on one plate; and, supposing one of them is printed too dark by one-half (which would make it perfectly useless were it an albumen print), I hold the plate opposite the dark shade and pour from a graduate glass or small pitcher a strong and hot solution of bicarbonate of soda on it, which will bring it into the same state as the other three in very short time. By using the soda the reduction is even and soft; the print loses nothing in detail as it would with ammonia.

Instead of using waxing solution for my glass, I use "French chalk"[†] or soap stone. By using this the pictures never leave the glass until you help them, when they will come off perfect.

Clean the glass with alcohol one ounce, nitric acid five drops, before powdering them with the chalk, which I do with a tuft of cotton.

* *Anthony's Photographic Bulletin.*

† It is as well to note that we think the wax solution better from the fact that the French chalk always leaves a haziness or fog, which detracts very much from the beauty and brilliancy of the results.—Ed. A. P. B.

THE PHOTOGRAPHIC EXHIBITION.

THE exhibition which was opened on Tuesday evening promises to be a success. A general impression had prevailed for some time previous to the opening that it would be a good exhibition. The bitterness arising from the agitation which bid fair to destroy the Society a few years ago appears to have been dying away, and a spirit of co-operation and unity again springing up. And the result is, we think, shown in the exhibition. In numbers alone this year the exhibition is unusually satisfactory, the number of contributions catalogued being five hundred and sixty-five as against three hundred and fifty-two last year. And there are upwards of two hundred pictures rejected, we understand, not for want of excellence, but want of space. In the matter of quality we think the exhibition is, on the whole, a still greater advance. There is a very high average of good work, and there is some superb work. There is, moreover, great variety of style and effect. Technical excellence seems in this day to be taken for granted as a matter of course; but we have much very exceptional technical excellence, and also a very gratifying display of pictorial qualities. The general effect of the hanging is very satisfactory; whether it may be found so throughout in detail is probably doubtful. The task of an amateur hanging committee is an arduous and a thankless one, involving much sacrifice of time, a good deal of actual labour and worry, and generally issuing, if not in failure, at least in much discontent. The duty of hanging the pictures in an exhibition requires for its successful carrying out much experience, much patience, and plenty of time, besides fine taste, good judgment, and a strictly impartial mind; and it is almost hopeless to expect all these conditions combined in a scratch hanging committee generally impressed into the work because the gentlemen forming it are sufficiently amiable to devote the time and accept the responsibility, despite its thankless character.

Prominent amongst the exhibitors whose work has been sadly missed at the last three or four exhibitions, returned this year, is Mr. H. P. Robinson. And he has made his return worth note by the contribution of one of the finest works of art of the many he has produced. In the place of honour, in the centre of the wall opposite the door, is hung the picture to which we referred some months ago as in preparation by Mr. Robinson for this exhibition, entitled "After the day's work is done." The picture is of large size, and represents a cottage interior lit by a small lattice window, through which a delicious glimpse of distant landscape is obtained. Seated at a table is an aged peasant with a large book before him—presumably a bible. The extended forefinger of the fine old man, tracing the line as he reads, suggests that some little effort is called into exercise in reading, and the eye must be assisted to

grip the line by the tracing of the finger, the whole aspect of the reader suggesting that he is not engaged on a facile task. On the other side of the table, and manifestly listening to the uttered words of the reader, is an old lady, clearly his wife, and both wear the calm and comforted aspect which the sacred words induce. A grand solidity and massiveness of light and shade characterise the picture, shadow largely prevailing, as, in a cottage interior at eventide, it must inevitably do. But there are no black opaque shadows. The deepest shade is rendered luminous and transparent by reflected light carrying detail into the darkest gloom. We noted that a crowd was generally gathered round this picture, and that the most eager amongst its admirers were invariably the men of the highest culture and art capacity amongst photographers. Specific pictorial attempts are not numerous in this exhibition, but there are some very fine pictures. Mr. Slingsby, of Lincoln, as usual, contributes something well worth looking at. His picture is entitled "Alone," and accompanied by a couplet descriptive of the scene—

"The tiny wavelets ripple to the shore,
And hush the tale of days that are no more."

A graceful female figure is seated by the sea shore in musing loneliness. The light draperies are treated with great skill and tenderness, and the sea rippling towards her feet: the sky and general landscape effect are simply delicious. A perfect sense of calm prevails, and the picture is full of daylight. It is full of atmosphere and space also, and that without any grey mists hanging about. The sense of space is perfect, and the looker-on feels that he could walk round the figure. In every detail the picture is a noble one. Mr. Faulkner sends several frames of the charming pictures in the production of which he is *facile princeps*. The almost infinite variety of infantine beauty he gives in his frames of small pictures requires much time to appreciate, and never wearies. But the great pictorial charm is in his carbon enlargements on porcelain with artistic finish. These, in many respects, are the gems of the exhibition. One of the most charming of these is a severe test to the spirit of charity and tolerance with which we have resolved to regard the labours of the hanging committee. We can see, partially, how exquisitely delicate and beautiful the picture is; but it is hung so high that it is impossible to examine its detailed perfections without the aid of a step-ladder, or opera glass. As we cannot readily avail ourselves of the first, we shall on another occasion try the aid of the second. A similar oversight in hanging is found in the microscopic enlargements exhibited by Mr. Viles. These are of unusual size, and, apparently, very fine; but the especial point of interest in such enlargements—perfection of definition—cannot possibly be examined, hung as they are far above the eye-line. One more case came under our attention. A subject picture, in carbon, by Mr. Higginson, entitled "La Somnambula," is a poetic picture of very low tone 'and great delicacy; but it is so far above the eye that it not only escapes attention, but cannot be examined with care. Mr. Higginson is doubly unfortunate. A couple of pretty figure studies of girls, entitled "Spring" and "Autumn," are numbered on the frame "49." Turning to No. 49 in the catalogue, we find it given as "Sheire Church," by Lieut. L. Darwin. Mr. Higginson's title and name being nowhere to be found. This is due to the haste with which the catalogue is inevitably prepared, and will, doubtless, be corrected in a second edition. We may note here, in reference to these two studies by Mr. Higginson, that they are not only very fine studies, but are good examples of combination printing in carbon, each having been produced from three negatives. We may remark, in passing, that carbon, although not very extensively represented, is in all cases most excellent. Amongst the noteworthy pictures which excite attention are some exceedingly charming landscapes by Mr. Crawshaw, and some fine groups by the same gentleman. His

photograph of Brecon is one of the finest landscape views in the exhibition. Mr. Blanchard has some fine portraits and single figure studies. A study of a Greek girl, entitled "Keolanthé," is exceedingly charming. Col. Stuart Wortley has some fine studies of clouds and sea, seriously marred, we regret, in more than one instance, by curious errors in the combining of two negatives in one print; in one case the sun, and the stream of reflected light from it on the water, not being in one line. A pleasant feature of this exhibition is a fair proportion of contributions from foreigners, and generally of very high quality. Herr Taeschler sends some very fine figure studies, illustrating his method of modifying the background by touching on the back of the negative. Herr Bernard Mischewski sends some exceedingly fine large heads, described as taken direct by Dallmeyer's 6A lens in a marvellously short time. Mr. G. Nesbitt has some very artistic and technically perfect figure studies. Mr. Ford Smith has some good subjects produced by combination printing. Mr. J. M. Young, of Llandudno, has also some very fine studies. Mr. S. Fry exhibits some figure studies, of which 335, "The Taxidermist," is very good. The arctic photographs exhibited by the London Stereoscopic Company are exceedingly interesting. Mr. Warnerke's contributions illustrating the use of his tissue will be found exceedingly interesting. There are many fine studies of animals to which we must refer in detail in future. M. Klary, of Algiers, exhibits examples of his mode of lighting which will interest many. We cannot here, in a general view of the gallery, even barely name a tithe of the contributions worthy of notice, as we briefly indicate only some of the contributions which arrested our especial attention on a first visit.

It should be noted, however, that the opening soiree was exceedingly well attended by an animated and interested company of ladies and gentlemen, the occasion, as well as the exhibition, being apparently eminently successful. We shall commence some notes on the pictures in detail in our next. The medals will be, we believe, announced at the November meeting of the Society.

FRENCH CORRESPONDENCE.

FOX TALBOT: HIS GENIALITY & CHARACTER—DRAPER'S DISCOVERY OF OXYGEN IN THE SUN—LIESEGANG'S PHOTOGRAPHIC MANUAL—CAPTAIN WATERHOUSE AND PHOTO-ENGRAVING—BOIVIN'S DRY PLATE METHOD: MODE OF PREPARING HIS PLATES—BOIVIN'S ALBUMEN PROCESS.

ALLOW me to add one word of regretful remembrance to the obituary notice devoted in your last to the memory of Mr. Fox Talbot. I had the honour of meeting him frequently some time ago, and when he visited Paris he did not fail to give me a friendly call. He had always much to tell me, and I learnt a great deal from him. Perhaps the friendly interest which he felt in me arose from my championship of his rights in France, where I upheld his claims always. A medallion on the frontispiece of the *Moniteur* shows him in combination with Niepce and Daguerre, and from my having designed this, which has been copied into almost every book on photography that has appeared in this country, he may have felt himself in some degree beholden to me. Whatever there was between us, I appreciated to the full the goodwill of the illustrious inventor, and that spirit of justice which pervades all who have made great discoveries. Mr. Fox Talbot in his relations with me always appeared filled with modesty, sincere, and characterized with gentleness, at a time, too, when, from the opposition and ingratitude he experienced, one might well have expected some degree of irritation. I am very happy indeed to be able to render this testimony to his memory.

The *Compte Rendus* of the Academy of Sciences which has appeared this week, and which contains the communications made on the first of October, embraces a memoir

of Mr. H. Draper upon his beautiful discovery of oxygen in the sun, and upon the new theory of the solar spectrum of which it is the result. A photograph of a very interesting nature accompanies the work, and it is, I believe, the first time that photography has served to illustrate this branch of science. The image of which I speak shows in its upper portion the spectrum of the sun, while the lower part is that of the spectrum of oxygen and nitrogen in the air. The photograph, as may be supposed, has not been retouched in the least, and the oxygen, iron, and aluminium are perfectly distinct. The print has been produced by the Albortype process from a negative of Mr. Draper's. The same was secured with a wet collodion plate which was so constituted as to support a fifteen minutes' exposure without losing any of its sensitive qualities.

Dr. Liesegang is about to publish in the French language a work of an eminently practical nature, and which cannot fail to be thoroughly welcome. We have already had an opportunity of seeing the proofs of the volume, and among them we found one article especially excellent, upon obtaining brilliant clichés by a wet collodion process. It constitutes in itself a veritable treatise of practical photography. One chapter upon collodion emulsion, and another upon gelatine emulsion, find a place in the volume, and they are both very interesting, while a very good chapter upon albumenized paper is also there. Nor is carbon photography forgotten, for we have a number of observations on the subject. Woodcuts in plenty accompany the text, and augment still more the clearness of the operations described by an experienced author whose name has been known for a long time by his works.

Captain Waterhouse, attached, as my readers know, to the Surveyor-General's Department at Calcutta, writes me that he has recently made some experiments with a process of photo-gravure based upon that published by M. Geymet. Although his results have been satisfactory, Captain Waterhouse thinks it advisable to wait awhile till the process is complete in all its details; we may therefore shortly expect an interesting and valuable communication from this officer.

In a letter which he has just sent to me, M. Boivin enters into a description of a dry process which yields plates quite as sensitive in their way as those prepared by the wet method. I have seen prints obtained by the aid of this very simple method, and I must declare that they appeared to me in every way excellent. The plates, covered with a preliminary coating of albumen, are collodionized in the ordinary way, and sensitized in a bath composed as follows:—

Water	...	100 cubic centimetres
Nitrate of silver	...	8 grammes
Acetate of lead	...	1 gramme
Acetic acid	...	a few drops

They are immersed without washing in a solution of chloride of sodium (1 gramme dissolved in 1,000 of water) to which has been added 1 decigramme of gallic acid. The plates are then washed in pure water and allowed to dry. In this way there is formed chloride of silver, which acts as a preservative, and some traces of gallate of silver, which adds to the sensitiveness of the film. Prepared in this way, the plates may be said to be capable of being preserved for an indefinite period without losing a trace of their sensitiveness, if only the operations are conducted with the necessary care. The time required for exposure is the same as that necessary for a wet plate. It varies, as a matter of course, with the lens employed, the opening of the diaphragm, the intensity of the light, and the nature of the subject. But, as with all dry processes, it is well to prolong the exposure, and this can be done exceedingly well with the plates, since they have no tendency to become solarised by over-exposure. I repeat that the results I have seen leave nothing to be desired.

A propos of M. Boivin, I may mention that many photo-

graphers have recently written urging me to call attention to that gentleman's albumen process, which he published two years ago, and which I reproduced in the columns of the PHOTOGRAPHIC NEWS. My correspondents tell me that the process is so very simple by reason of the circumstance that most of the operations may be conducted in full daylight.

ERNEST LACAN.

PHOTO-SPECTROSCOPY.

BY CAPTAIN ABNEY, R.E., F.R.S.*

As regards the kind and number of prisms to be employed, there are various opinions on the subject. The object for which the spectroscopic work is required must be taken into consideration. If, for instance, it be desired to determine the limits of sensitiveness to the spectrum of any particular compound, it will be found that one large prism is preferable to a larger number of small ones; and again, it is not so absolutely essential in this case the prisms should be "above suspicion" as regards the perfection of their surfaces, since any small error would not appreciably affect the result. It must not be supposed that a prism of any description, such as that from a gaselier, will answer. There are limits beyond which imperfections will give inaccurate results; but the inference which I wish to be drawn is this, that if a prism have fairly worked surfaces, then for the purpose of testing the sensitiveness of different compounds a very exact defining power is not an absolute necessity. Thus, I have found that the hollow bottle prisms filled with carbon disulphide, such as are supplied by dealers for class experiments with the electric light, are quite good enough to employ, at all events, in preliminary examination. It may be asked, Why, then, have such a perfect collimator as has been described? The answer to this is, that a good collimator costs but very little more than a rougher one, and it can be used for the most delicate experiments, and it is always well to have a slit the opening of which can be ascertained with accuracy, since with even a rough prism, most important results may be obtained as to the sensitiveness of compounds with differing intensities of different coloured rays.

It would be better, on the score of economy, that the experimenter should provide himself with a really fine prism at first, since it is almost certain that after a few experiments with the rougher one his ambition will be raised, and he may wish to use it for photographing metallic spectra, or for noting absorption bands and lines. A dense glass prism of some two and a-half inches wide and one and a-half inches high, having an angle at the apex of the polished surface varying between 60° and $62\frac{1}{2}^\circ$, will answer almost any purpose. Some opticians supply these prisms with the top bases and backs merely ground to give a dull appearance. With such (particularly if it have the larger angle as given above) the operator should beware, as there is often false light introduced into the spectrum by reflections. The remedy is simple: give them a good coating of dead lamp-black on the ground surfaces. Unless a diffraction grating be used for obtaining spectra, there is always a certain amount of light diffused through the body of the glass itself, owing to glass being a turbid medium (though for ordinary practical purposes it is perfectly transparent), and in some experiments which I undertook it had a disastrous effect. This, however, cannot be got rid of, except by carefully studying the necessities of each case, and cutting off any particular ray which might prove annoying. I may particularly remark that if it be desired that as much light as possible should fall on the plate, the apex of the prism need only have an angle of 40° to 45° , since the reflection from the surface is diminished as the angle with the normal to it is diminished. To mount the prisms, procure a perfectly flat slab, ground with great precision and of the necessary dimensions, so that it is a practically plane plate. Then raise it on a stand resting

on a tripod, so that when the prism is placed upon it the centre of the prism is of the same height as the centre of the collimating lens.

The table on which the collimator, prisms, and camera are placed should be perfectly steady, and, if possible should rest on the ground and not on a boarded floor since the vibrations of the latter caused by footsteps, &c., are apt to be communicated to the table and thence to the apparatus. If it is merely the sensitiveness of compounds that is being studied, this is not of so much consequence; but in studies of this description too much care can never be taken, however rough they may be, for we all know the old proverb about the formation of habits.

We next have to consider the lens that should be used. One point is essential: it must be of at least equal diameter with the height of the prism, otherwise a portion of the beam of light may pass outside it, or strike on the mounting and lead to reflections, which may prove very bothering. As to the focal length of the lens, that, again, must depend on the nature of the work undertaken; if it be required simply to ascertain the sensitiveness of compounds, it may be much shorter than if used for mapping the solar spectrum. I do not advise, under any circumstances, a less focal length than ten inches, as below that with one prism (with which you can get the brightest possible spectrum), the length of the spectrum impressed on the plate would be too small to be satisfactory. Calculation will show that if you gain the same length of spectrum by using two prisms with a lens of five inches focus, as you do by using one prism with ten-inch focus, that the brightness of the light is superior in the latter case.

It also must not be lost sight of that the violet end of the spectrum loses its intensity by passing through a series of prisms more rapidly than over the red end, since the angles, measured from the normal, at which the former rays strike the surfaces of the prisms, are always greater than of the latter rays, and therefore more of them are reflected. For the determination of lines, &c., a lens of focal length of from four to six feet is desirable. It is by no means necessary that the lens should be achromatic, though what has been said regarding the collimating lens applies in this instance. A few shillings should purchase a non-achromatic lens which is suitable, and two or three more may be spent on the mounting of it.

Part of the camera may be manufactured at home if thought advisable. It should be of about whole-plate size, so that a plate eight and a half inches in width may be used; the dark slide should have an inner frame to carry a plate (say) eight inches by two. The necessary length can be secured by making a light wooden frame of such dimensions as just to fit against the camera. When a rigid front board is fastened at the end to carry the lens, the frame is covered with two thicknesses of brown paper, and a good coating of lampblack given to the inside, and this part is complete, except so far as attachment to the camera is concerned. It is a good plan to carry the framework and the camera on a flat board, and fasten them both down to it, leaving, of course, the focussing screw free to work.

It will be apparent that the camera must be of that kind which focusses from the back. It is very desirable also that there should be a horizontal swing back to it, since a better general focus can be obtained by using it.

THE PRODUCTION OF PYROXILINE FOR PHOTOGRAPHIC AND MEDICAL PURPOSES.

BY W. GODEFFROY.*

AMONG the numerous receipts for the production of pyroxiline the following holds as one of the best:—

Saltpetre	560 grammes
English sulphuric acid	...	420	"
Fuming	...	420	"
Cotton wool, oil freed...	...	70	"

* Continued from page 484.

* Zeitschrift Allgemein Osterr. Apoth. Ver eins.

I have repeatedly employed these proportions, and have obtained, as result, a pyroxiline that for the most part dissolved in the ether; the solution was, nevertheless, cloudy, and always showed small particles of undissolved wool floating in it, rendering the collodion useless for photography, and only applicable to medical purposes after long standing and waiting. I sought for the cause of this unsatisfactory result in the saltpetre used, fearing the latter might be in too damp a state; I dried the same, therefore, in a large mortar, and, when cold, employed it again, but with no better success.

One day, requiring some collodion in a great hurry, I neglected to take the mortar, together with its contents, from out the sand-bath, and after having added the acids, I simply placed the oil-freed cotton wool in the mixture. This time I obtained a pyroxiline which dissolved in the ether completely without residue. My idea as to warming of the mortar, together with the mixture, to a certain degree, being necessary for a favourable result, was consequently borne out, and I obtained thenceforward a wool that always dissolved completely in the ether, taking the precaution at the same time to leave out the fuming sulphuric acid, and to replace it with English acid.

The temperature at which this experiment was conducted, with the saltpetre in the mortar, was 56° Cent., and the action of the acids on the wool lasted seven minutes. The component parts were proved to exist in proportions as follows:—

Cotton wool	35 grammes
English sulphuric acid ...	700 "
Saltpetre	350 "

The freeing of the cotton-wool from oil is done in the regular way, by warming in a solution of soda, and a short boiling in water to which a small quantity of caustic potash has been added; lastly, it is thoroughly washed out in distilled water.

The cotton thus prepared is dried and well picked out, and then placed with the above-mentioned proportions in the mortar. It is stirred well with the pestle, so that it comes thoroughly into contact with the acids, and is allowed to remain immersed for seven minutes; afterwards it is quickly removed into a large vessel of hot water, and then placed under a stream of cold water till every trace of the acid has disappeared. Finally, it is washed several times in distilled water.

This compressed pyroxiline should be then picked out, and at once dissolved or covered with damp sand.

ON THE PRESENCE OF HYPOSULPHITE OF SODA IN MOUNTING BOARDS.

BY DR. H. VOGEL.*

RECENTLY instances have repeatedly occurred of the presence of hyposulphite of soda in cardboard, and the subject has therefore appeared to me sufficiently important to warrant investigation. Both from North and South Germany specimens of doubtful cardboard were forwarded to me, upon which pictures had in time become yellow under circumstances which seemed to preclude the idea that the defects could be traced to any other source.

The samples of cardboard to be examined were cut into pieces, and placed in lukewarm distilled water for the space of twelve or twenty-four hours, and the resulting liquid then tasted with iodine starch. To prepare this latter material one gramme of iodine was dissolved in twenty-five grammes of alcohol, and this was diluted with 625 cubic centimetres of water. A solution of starch was then prepared by boiling one gramme of powdered starch in 100 grammes of water, and 25 cubic centimetres of this was mixed with one cubic centimetre of the diluted iodine solution. In one cubic centimetre of this blue starch solution

there was $\frac{1}{15625}$ of a gramme of iodine, and the admixture of it with water in which the card had been steeped brings about a gradual bleaching of the tinted starch.

In order to make a reliable experiment, two perfectly clean test tubes should be taken, and having been placed close together, one cubic centimetre of the iodine starch is placed into each; to the one is then added fifteen cubic centimetres of pure distilled water, and to the other the same amount of water in which card has been steeped. By shaking and comparing the tints of the two fluids, it is evident whether or not a bleaching of one of the liquids has taken place; any bleaching action being due to the oxidation of hyposulphite of soda. The following equation will demonstrate this:—

Two equivalents of hyposulphite of soda, therefore, absorb one equivalent of iodine. The atomic weights of crystallized hyposulphite and iodine are nearly equal, the former being 124, and the latter 127, and one part by weight of iodine will therefore neutralize two parts of the soda salt; it is easy, therefore, to calculate the amount of hyposulphite in any cardboard under examination.

For instance, I steeped three carte-de-visite cards in 100 cubic centimetres of water, and of this I required 14½ cubic centimetres to bleach one cubic centimetre of the iodine starch of the strength above referred to. It follows, therefore, that 100 cubic centimetres of the water sufficed to bleach seven cubic centimetres of the starch. The latter contains $\frac{1}{127}$ of a gramme of iodine, which will neutralize $\frac{1}{127}$ of a gramme of soda, and therefore one carte-de-visite card contained about $\frac{1}{15625}$ or $\frac{1}{125}$ of a gramme of hyposulphite of soda.

Manufacturers may deem such quantity to be very little possibly, but that this amount is of influence it is easy to prove. A sheet when attached to a silver print contains on an average 0.075 or $\frac{3}{4000}$ gramme of silver, and a carte-de-visite or $\frac{1}{36}$ of a sheet $\frac{3}{4000} = \frac{1}{480}$. Therefore the carte-de-visite contains 6.6 times as much silver as the card does hyposulphite of soda. Now 31 parts of hyposulphite are sufficient to act upon 27 parts of silver, and convert them into sulphide of silver, and therefore we find that the amount of soda in the carte-de-visite is enough to convert one-eighth of the silver into sulphide of silver. And as, moreover, the silver is very unevenly spread over the surface of a picture, the high lights containing much less than the shadows, the amount of soda above mentioned is quite sufficient to bring about a change of the silver in the high lights or whites of the picture.

Photographers who desire to make an experiment such as here recorded, must be enjoined to undertake it with the greatest care. All vessels and test tubes employed, as also one's hands, must be scrupulously clean. Those who conduct such experiments after performing fixing operations, and carry about with them traces of soda, may be led into making very grave mistakes.

The testing fluid must always be employed quite fresh. One gramme of iodine is dissolved in 25 cub. cents. of alcohol, and 2½ cub. cents. of this solution is diluted with 900 cub. cents. of pure distilled water, and 100 cub. cents. of starch solution is added. This liquid then contains precisely $\frac{1}{15625}$ gramme of iodine. The experimenter should then proceed as in the manner I have indicated.

It is a question whether cardboard which has been proved to contain hyposulphite can be rendered serviceable. I believe it can. It is only necessary to treat the card with some substance which will decompose the hyposulphite without injuring the picture, and such a substance is iodine.

The illustration I have given above shows that 7 cub. cents. of iodine solution 1:15625 was required to decompose the soda in three cartes-de-visite. It is only necessary, therefore, to moisten the cardboard with about double as strong a solution of iodine solution in order to render

* *Photographische Mittheilungen.*

the hyposulphite altogether innocuous. Dipping in iodine water would be quite as effectual. The small quantity of superfluous iodine would rapidly evaporate on the drying of the cardboard.

Admixture of iodine to the starch or paste employed in mounting the photograph might answer the purpose equally well of neutralising the action of any hyposulphite contained in the mounting board. I cannot, however, yet say whether such a proceeding would be advisable until I have made a few experiments on the subject.

Correspondence.

RETICULATION IN CARBON.

DEAR SIR,—My experience has been so decidedly different from Mr. Witcomb's that I should like to lay it before the chromotyping fraternity, that we may discover the reason. First, then, like Mr. W., my satisfaction with chromotypes increases: also the public's, as is evidenced by my daily increase of that work, at an advance in price of 25 per cent. over the silver. There is little danger of over printing, as, with bicarbonate of soda and hot water, a very dark print can be reduced without any loss in half-tone.

Reticulation—on this side of the water, at least—is very troublesome to many yet, and has been especially to myself until lately. The way to steer clear of it is directly opposite from that of Mr. W.'s. I am now using a sensitive solution of one ounce bro. potas. to ditto of water, to my best satisfaction. Since using a weak sensitive solution I haven't seen reticulation. Of one thing I am positive, that quick drying won't produce it in my sensitive solution. When I used one ounce b.c. potas. to thirty water in summer, I had continual reticulation. I can use the tissue to first-class advantage, four and five days after sensitising in hot weather, but could not when using the strong solution.

I find the morning the best time to begin developing the previous day's work. I use a vertical trough, and when the paper is stripped I put the prints into water at from 84° to 86°, when I can go about and attend to any other kind of work, and return to give the final rinse to the prints in half-an-hour, or, if need be, in two or three hours, as convenience allows; in either case they are always ready, and no danger of the half-tones being washed off. Though more time is taken to develop in this way, yet there is less time consumed, as the developing goes on itself, and to much better advantage.

I must say my experience in the washing up of the high lights and loss of detail have only been when I was using a three per cent. sensitising solution, and not since adopting the weak one, as Mr. W. says is the bether of the photographers in carbon printing.

I have no doubt but our Canadian climate may have something to do with these discrepancies, but where is the difference, if the ends attained are alike? And to be satisfied on that point, I hope Mr. W. will send me a sample for exchange; and also any other successful chromotype worker, as I think an exchange of prints might be equal to an exchange of ideas. The one would at least help the other. So some of you try it.

Montreal, September 28th.

J. INGLIS.

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

A MEETING of this Society was held on the 4th instant, the Rev. F. F. STATMAN, M.A., F.G.S., &c., presiding.

The minutes of the previous and out-door meeting having been read, Mr. Houghton and Mr. Malony were elected as members.

Mr. Brooks read a paper on "Spots on Emulsion Plates; Their Cause and Cure" (see page 483).

In course of a desultory conversation on emulsions, Mr. Brooks, in reply to a question, said that at present he would rather not publish the details of the emulsion process he employed. He preferred to dry his plates by means of a hot water bath which he exhibited. A vote of thanks was awarded him for his paper.

The SECRETARY intimated that the Annual Technical Exhibition of the Society would be held on November 15th; the ordinary monthly meeting to take place on the 1st.

There being no other business, the proceedings terminated.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE first ordinary meeting of the season was held in 5, St. Andrew Square, on the evening of Wednesday, the 3rd inst., the President (Mr. LEASDALE) in the chair, when the minutes of previous ordinary and out-door meetings were read and approved; and Messrs. T. W. Drinkwater and John Todd were admitted ordinary members.

Dr. HURTER exhibited a large collection of water-colour and other sketches of scenery in the Highlands of Scotland and North of Ireland (with a view, in the first place, to offer suggestions to photographers), of localities rich in the picturesque, and also to seek information as to the best means of getting them reproduced by photography, and how best to finish them for that purpose. The exhibition elicited a good deal of discussion, the outcome of which was, that the sketches should be finished in monochrome, with Indian ink warmed up a little with brown, or in grey; and that such of the mechanical processes for printing in carbon as was found most suitable in the relation to the number of copies required, be selected.

Mr. W. T. BASHFORD then read a paper entitled "Odds and Ends," which turned out to be a review of the work of the Society during the past four years, and in which he found fault with much that had been done, both as regards the work itself and the manner in which it had been accomplished. He also expressed a wish that the business of the ordinary meetings should take a more practical form, and that, for the benefit of younger members, such elementary proceedings as the coating of a plate with an albumen substratum should be shown and illustrated.

Dr. THOMSON said that Mr. Bashford was generally so practical in his observations, and had frequently such interesting information to give, that he had come to the meeting on purpose to hear him; and, while he did not agree with all that he had just heard, he had listened to the paper with much pleasure, as it contained some valuable suggestions. But, as he had not had time to digest the subject, he could not at present say more on it.

Mr. DONNIX agreed with all that Mr. Bashford had said. He knew, from his long experience, that he would have something to say that was worth listening to, and had come to the meeting on purpose to hear it. Although the Society numbered over three hundred, the business was mainly conducted by about a dozen. So long as the Society agreed with them all went well, but when it did not do so things were not so pleasant. He believed that, although the influence of the popular meetings was of a transitory nature, they had added much to the membership of the Society, and thought that the practical papers suggested by Mr. Bashford would do much good.

Mr. MACGIBIN thought that if instead of always having regular papers, which often serve no practical end, each member would from time to time bring specimens of his work, it would give rise to discussions of much value, and elicit much useful information.

The business then took a conversational turn, the subject being the relative advantages of collodion and gelatine emulsions for the preparation of dry plates.

The PRESIDENT stated that he had recently tried those prepared by Messrs. Gray and Truett with the gelatine emulsion introduced by Mr. Gray, and found them better than anything he had yet used. They were quite equal to wet collodion in rapidity, and developed into clean, beautiful negatives.

Dr. THOMSON had recently seen a lot of portrait negatives, both on collodion and gelatine films, and had no difficulty in picking out the best, and they were all gelatine.

Votes of thanks were given to Dr. Hunter and Mr. Bashford, and the meeting adjourned.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE Board of Management held their monthly meeting at 174, Fleet Street, on Thursday, October 4th.

The minutes of previous meeting having been read and confirmed, the subject of removal of office was then considered, and, after some discussion, the following resolution was passed:—"That the Secretary be authorized to give due notice of removal of the Society's business from 174, Fleet Street, and that he engage the room at 160A, Aldersgate Street, E.C., as the Society's office, upon the terms placed before the Board." At which place the Board of Management will meet on the first Wednesday in every month, at 8 p.m., instead of Thursday, as previously. Members are requested to note the removal in their rule books, &c.

The meeting then adjourned till Wednesday, November 7th.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE annual meeting of this Society was held as usual at the Museum, Queen's Road, Bristol, on Wednesday, 8th instant, Mr. BALGHTMAN in the chair.

The SECRETARY having read the minutes, which were confirmed, Mr. Redcliff, of London, was elected an ordinary member.

The SECRETARY then read the report for the past year.

"Your Council, in presenting the report for the past year, desires to congratulate you on the steady increase in the number of members, there having only been one indoor meeting at which one or more has not been elected.

"The following papers have been contributed by members, to whom the Association is greatly indebted, and tenders its best thanks:—"Intensification of Wet Plates with Iron," by Mr. E. Britman; "Light, Exposure, and Development," by H. A. H. Daniel; "Note on Photographic Chemicals—Their Adulteration," by W. W. Stoddart; "The Waxed Paper Process," by P. J. Worsley; "The Collodio-Albamen Process," by Dr. G. H. Thompson.

"The thanks of the Association are also due to the Committee of the Bristol Museum, for placing a room at its disposal on advantageous terms.

"The financial position of the Association is satisfactory, the balance of income and expenditure having been adjusted to within a few shillings.

"The monthly evening meetings have been fairly attended, although, looking at the attractiveness of the papers read, and subjects provided for discussion, there is room for improvement.

"Your Council regrets that the three outdoor meetings have been so poorly attended, especially as it was generally expected they would prove, if anything, the most popular. Your Council strongly urges and hopes that every member will do his best to at once resolve that few, if any, of the evenings announced on his cards for next session shall be engaged to the exclusion of the Association's meetings; it also hopes that the outdoor excursions will prove the popular meetings of the future, and that they will be attended by a larger number of working members. In conclusion, the Council urges the desirability of each, individually, doing his utmost to increase and popularize the Association."

LEUT. LYSAGHT moved the adoption of the report, which was seconded by Mr. BOYDEN.

The accounts, which had been audited by Messrs. Davey and Boyden, were presented and passed.

The Council for the ensuing year having been elected, the meeting was dissolved.

In June and August outdoor meetings were held, the first at Tynora, which was mostly of a social character, and the second at From Glos, near Bristol, at which nearly all present worked, the wind which prevailed, however, cramping the amount of work which might have been done. The July meeting was prevented from being held by the weather.

Talk in the Studio.

CAUTION.—A correspondent from Portsmouth writes to caution provincial photographers against a German calling to purchase waste residues, and then contriving to get away without payment.

PHOTOGRAPHIC ILLUSTRATIONS FOR THE LANTERN.—We have received from Mr. York a copy of a highly dramatic poem entitled "Jane Conquest," for which Mr. York has produced illustrations from life studies for the lantern under the direction of

Dr. Croft. Few things can add more to the interest of a lantern evening than the recitation of a good dramatic poem with effective illustrations on the screen; and the well-known excellence of Mr. York's slides must materially aid in giving vitality and interest to the poem in question.

FOUNTS BY A PHOTOGRAPHER.—We have been favoured by Mr. W. G. Harrison, a gentleman whose name is familiar in connection with photographic and other scientific literature, with a copy of a volume entitled "Lazy Lays and Pious Imaginings." Several of the lays refer to photographic matters, and will interest photographers. Mr. Harrison has considerable facility of versification, and deals, in pleasant and humorous mood, with many scientific follies which are better laughed down than gravely disputed.

IMPROVED FILTERING PAPERS.—We have received examples of a very important improvement in filtering papers, made by Mr. T. Bom, of Cape Town. It consists in the attachment to the circular filtering paper of a lining consisting of some open fabric like net or muslin. The examples before us have a lining of what is, we believe, technically termed *lene*, a kind of muslin of very open texture. This serves two purposes, each of vital importance. In the first place, it prevents the paper clinging to the sides of the funnel in a manner which checks the progress of filtration, and it also prevents the risk of an occasionally very troublesome danger, that of the soaked paper bursting with the weight of a bulk of solution, making a troublesome mess, and wasting the work of many hours. The advantages are so obvious that they do not require enforcing. The article is patented, and will doubtless soon find its way into the trade.

FATAL ACCIDENT.—The following particulars of a melancholy accident to a son of Mr. G. Willis, the well-known landscape photographer, to whom our readers are indebted for many valuable hints in connection with landscape work, are gleaned from the *Scarborough Weekly Press*. It appears that on Wednesday, 11th of July last, George F. Willis, six years old, son of the gentleman named, was playing with other children in the timber yard of the North Eastern Railway close to a crane which was being used in lifting and removing logs. The workmen told the youngsters to get out of the way, and afterwards, when they expected all was safe and clear, the break was released, and the handle of the crane spun round. At that moment the head of the child—George Willis—was seen to come in contact with the handle. He was struck down and his skull severely fractured; the brain protruding. Dr. Horne was called in to attend him, and pronounced the case a very critical one. However, the poor little fellow continued to linger in a precarious state until death ended his sufferings despite all that medical skill and knowledge could do to preserve his life. At the inquest, evidence having been given by Edgar Willis, elder brother of the deceased, Mr. Willis, the father, stated that about five weeks after the accident witness seated the deceased opposite the window in front of the timber yard, when he said, "There's the ball that knocked my head," alluding to the ball attached to a crane used in hoisting and removing wood. Witness said, "It's the handle you mean?" "No," he replied, "it is the ball." He added that a man asked him to hold the ball while he put a bar under some wood. When the wood fell the ball "jagged" his hands and he let it go, when it dropped on his head. Witness had seen the man several times since the occurrence, and he had asked his daughters how their brother was getting on. A juror stated that the man ought to have been present, as he was censurable in allowing the boy to hold the ball up. Another juror said he was of opinion that the injury was inflicted by the crane handle, and that the boy could never have lifted the ball up high enough. Dr. Horne said the deceased suffered from a scalp wound on the right side and toward the crown of the head. The skull was fractured, and the brain protruded. He had attended him since the accident until he died. The first few days he had very little hopes of the boy's recovery, but afterwards he rallied, and his case became rather more hopeful. He continued to improve until about a fortnight ago, when unfavourable symptoms set in, terminating fatally. The injury might have been caused by the falling of the ball, but he thought it more likely to have been occasioned by the revolving of the crane handle. Several jurors considered that the workmen were to blame in leaving the gates open, and thus rendering it easy for children to get into the yard. The jury returned a verdict of "Accidental death," with an addendum expressive of their censure of the man for allowing the deceased to take hold of the ball at all.

EFFORTS OF COLOUR IN THE STUDIO.—Referring to some curious experiments recently made in Italy by a physician for the insane, and in which light played an important part, the

question considered was the influence exercised upon the insane by their being kept in rooms lighted by red, blue, and violet glass. Mr. Silvy, who was for some years the most noted portrait photographer in London, says:—"As far back as 1860," says our correspondent, "I used this process, not for the complete cure of the customers who flocked to my ateliers, but at least for their momentary relief, and for my own advantage. Thus, the first rooms in which I received my customers were hung in dark green; the ceiling green, set off with oak; the windows furnished with green blinds; the curtains of green velvet, so as to afford rapid relief to the sight of persons who were more or less excited by walking or riding in the open air. After remaining a few minutes in these two salons, they entered a boudoir hung with pink chintz, in which the ladies made their toilets, and thence passed into my atelier, which was on the same floor with these three apartments. The gallery itself was divided into three parts, one completely darkened by hangings of green serge; the other, in which the light was subdued, by a coating of white paint, which gave to the panes the appearance of ground-glass. I had green trellises placed against the sashes, and at the bottom boxes of earth, containing ivy and vines, which ascended to the top of the gallery. There were only two or three open spaces through which the light entered freely. It was thus that I obtained my effects of crisp light."
